Toilet training would seem to be essentially an exercise in the development of a conditioned response, as the successful conditioning of a case of enuresis shows (Jones, 1956), inasmuch as an involuntary reflex has to become amenable to voluntary control. Dollard and Miller (1950) treat this problem at length in terms of a series of learned responses and come to similar conclusions, as do Mussen and Conger (1956). Most authorities agree, however, that the learning process should be delayed until the child is physiologically mature; thus the child should be able to understand and communicate with an adult fairly easily and he should be able to sit comfortably (English and Pearson, 1945; Gesell, Halverson, Thompson, Ilg and Costner, 1940; Hushka, 1942).

The learning theory approach is quite at variance with that of the psychoanalysts. According to the analysts, just about the age when it is agreed that a child is ready for toilet training (18-24 months), so he is in the second phase of personality development, namely the anal phase, as opposed to the earlier oral phase of the first year or so of life. In the anal phase the child is supposed to get pleasure primarily from anal activity. In the first phase of this stage pleasure is derived from expelling and in the second phase from retention. According to Freudian theory excessive indulgence or coercion during this phase may lead to fixation at this stage in later life and the development of what is called an anal character. As an adult the anal type is supposed to retain money as well as tend towards constipation; he tends to be mean, orderly, meticulous, cruel and aggressive (Fenichel, 1945).

Some of the implications of Freudian theory with respect to toilet training and personality development are difficult to test. For example, it seems impossible to tell with any degree of validity or reliability whether a two-year-old finds retention of his faeces pleasurable or whether he gets more enjoyment out of elimination. However, the existence of an anal character is easier to examine, since it can be considered in the older child or in the adult. Thus Sears (1936) has shown in male

students that the so-called anal character traits of orderliness, obstinacy and frugality are all positively intercorrelated. But there is little acceptable evidence concerning the relationship between these characteristics and early childhood toilet training.

It is known, however, quite apart from any theoretical considerations, that too strict toilet training or toilet training commenced too soon may actually retard the acquirement of bowel and bladder control (e.g., Whiting and Child, 1953). According to Despert (1944) toilet training is most readily achieved if the mother is calm and easy-going and herself exhibits no signs of distaste or disgust. An extensive study by Hushka (1942) of over two hundred children referred to a child guidance clinic as disturbed revealed that in over half of them bowel training had been too harsh or commenced too early, or both. She observed that in most of this subgroup the children had reacted almost immediately by maladaptive symptoms such as diarrhoea, constipation, fear, rage, guilt or excessive cleanliness. She also found that many of these children had been bladder trained far too early and had reacted adversely. It is difficult to generalize from these data to normal children, however, and there is a need for normative data.

There is some evidence which indicates that children toilet trained too early later tend to exhibit compulsive and rigid personality characteristics (Despert, 1944). There is other experimental evidence to indicate that over harsh toilet training is related to negativism and aggression (Sears, Whiting, Nowlis and Sears, 1953; Macfarlane, Allen and Honzik, 1954). A recent study by Beloff (1957) seems to provide evidence against the hypothesis that anal character results from method of toilet training although based on retrospective accounts of training. In a study of one hundred and twenty undergraduates, questionnaire responses were obtained to questions concerned with items corresponding to anal character traits. The traits chosen were obstinacy, "parsimony, orderliness, cleanliness, punctuality, procrastination, quasi-sadism in personal relations, conscientiousness, pedantry, feelings of superiority, irritability, desire to domineer, desire for personal autonomy."

Responses were compared with peer ratings of the one hundred and twenty subjects by four of their acquaintances. Responses of both when factor-analysed showed the emergence of only one significant factor. The correlation between the two factors was highly significant. It was therefore concluded that "a psychological functional entity" existed, corresponding to the character as described by psychoanalysts. However, this entity was not associated with toilet training experiences "but strongly to the degree of anal character exhibited by the mother." The procedure here was the comparison of age of completion of

toilet training as a measure of coerciveness and the completion of the questionnaire by the mothers as a measure of anal character. A 2×2 analysis of variance established the significance of the latter. In this part of the experiment the subjects were forty-three graduates.

The study has the methodological weakness of retrospective studies of toilet training, but the results are of great interest in view of their statistical significance.

In general the evidence is inadequate to arrive at any conclusions with confidence; but although the precise mechanisms or consequences are obscure, there is good reason to believe that too early or too stringent toilet training may well produce adverse effects. Research is required into the nature and permanence of these effects, the likelihood of their occurring and under what circumstances these effects are most likely to occur. In this respect it is also necessary to relate the problems associated with various forms of toilet training to the personality and pathology of the children concerned.

These are only some examples of the conflicting evidence concerning psychoanalytic theories of children's behaviour problems. Many psychoanalytic propositions at first appear to be common-sense everyday observations which make an appeal for this reason, but when interpreted seem to be rather unusual observations of an exciting kind. In either form they are hard to verify. Writers such as Farrell (1951) have despaired of establishing psychoanalytic hypotheses in their original form. Its effectiveness as a rationale in therapy has been frequently disputed (Curran, 1937; Eysenck, 1952) and after many years, even the fundamental axioms remain unestablished. The results reported in this section do not lead the authors of this chapter to expect dramatic changes in the effects of treatment to result from a regime dictated by psychoanalytic theories. In saying this and in drawing attention to the difficulties of proving analytic hypotheses whether genetic or dynamic we have followed Farrell's criticisms. It would, however, be ungenerous and quite false to ignore the impact of Freud's contribution in directing attention to such matters as childhood sexuality and such plausible mechanisms as regression, projection and denial in relation to maladjustment. The consistent demand of analysts is that such phenomena should be explained. In calling for an explanation in terms of a meaningful interpretation it seems to us that they may be mistaken, just as it would be incorrect to try to interpret the verbal statements of some schizophrenics. However, such an opinion needs to be established and, so far, alternatives to psychoanalytic views have not been advanced. In this section we have tried to draw attention to the shortcomings of the analytic proposi-

tions. In the final section attention is drawn to some of the alternatives which learning theorists are beginning to advance.

Sensory Deprivation and Behaviour

Theses concerning isolation whether social, personal or physical have recently been resurrected after long neglect and their refurbishing has been undertaken in many different ways. Probably the foundation of these theories can be found in the stories of feral children and the classic study of the wild boy of Aveyron (Itard, 1932). However, more recently the inspiration for such work comes primarily from studies made by Hebb (1949), Thompson and Heron (1954) and others. Itard's study of the boy of Aveyron and Seguin's (1846) subsequent work with idiots have a link with this more recent work in so far as both have a similar opinion concerning the importance of sense training at an early stage.

Hebb (1949) makes early learning critical for later learning because he suggests that the entities of perception are themselves complex and not given as maintained by Köhler (1929) but based on experience. The justification for a statement of this kind has in recent years become more experimental than philosophical. In this section the experimental data will be reviewed with the intention of keeping in mind later disturbances of behaviour or other relatively permanent effects.

The impetus of this movement comes essentially from studies of children suffering social isolation. One of the earliest studies was that of Hill and Robinson (1929). Another source is undoubtedly the Iowa studies of the pre-war and post-war years. A study of the relevant material is that of Wellmann (1945). This school, despite certain earlier criticisms of their statistical procedures, has now succeeded in showing that some early loss of experience can be made up by education. Similar results have been reported by Clarke and Clarke (1954) with patients diagnosed originally as feeble-minded.

Theoretical development of learning and perception have made the biggest contribution. Hebb (1949) has laid great stress on early learning and its importance for later learning. His point is that even schemata may be learned and that such early learning is not only extremely slow and inefficient but also basic to later learning.

Hebb discusses the evidence for this conclusion and refers also to Hunt's (1941) experiment with the hoarding habits of rats and their connexion with earlier hunger experiences. The experiment referred to is only one of a number of similar studies which can be generally comprehended under the heading of deprivation. Maternal deprivation is discussed elsewhere in this chapter and might be said to be a special

case of deprivation. To some extent, the confusion centring round this particular discussion has not prevented other theoretical issues from emerging clearly.

Since the studies at Iowa, a number of investigations have made apparent the disabling consequences of social, educational and emotional isolation with children and the effects of sensory deprivation with animals. Among the better examples of this work are the studies of Thompson and Heron (1954), Davis (1940), Bingham and Griffiths (1952) and Hebb (1947). A recent reappraisal of this work in the field of sensory perception is that of Zuckermann and Rock (1957).

The most succinct statement, however, of the relevant theoretical issues has been made by Hebb (1949) as follows—

If the learning we know and can study, in the mature animal, is heavily loaded with transfer effects, what are the properties of the original learning from which these effects come? How can it be possible even to consider making a theory of learning in general from the data of maturity alone . . . transfer from infant experience may be much greater and more generalized.

G. A. Ferguson discussing this view in the *Canadian Journal of Psychology* for 1954 says: "In many adult learning situations, the most important variables exerting transfer effects on subsequent learning are the 'abilities'—the prior acquisitions that have attained their limit of performance." He goes on to argue the case for a theory in which learning depends on different combinations of abilities at different stages in learning and whereby some circumstances will completely prevent learning of some kinds: "An individual may possess the necessary ability to perform a task adequately, but may lack the ability to learn to perform the task under particular learning conditions." (Op. cit., p. 110).

The dispute concerning the origins of the basic abilities continues, and despite the extensive and good experimentation carried out in Canada, an article recently written by Zuckermann and Rock (1957) attempts to question the evidence for the effects of early experience in favour of a gestalt-oriented theory of innate perceptual processes. They say—

One can hardly take a dogmatic position in an area where, as yet, there exists so little decisive experimentation. Nevertheless, it is important to determine the status of a scientific theory in relation to present knowledge. On the basis of logical analysis and an examination of relevant evidence, we have argued for the thesis that various aspects of the phenomenal world and, in particular, the segregation and shape of visual forms are given by innate organizing processes. Percepts may be modified and enriched by experiential factors, but

the effects of such factors presuppose the prior existence of visual forms.

If the thesis defended in this paper is correct, perceptual organization must occur before experience (or personality factors which depend on experience such as need, purpose, and value) can exert any influence.

The case put forward in their article involves some special pleading, but also includes a reconsideration of some of the early work of von Senden (1932) producing arguments based on Michael Wertheimer's (1951) criticisms. These criticisms are presented as follows—

On the human level, the data consist of observations made on cases of congenital blindness (due to cataracts) to whom vision was restored in later life by surgical operation. The literature on such cases has been analyzed by von Senden (1932) and his study is often cited in support of the empiricist theory. According to Hebb, for example, these patients could not immediately distinguish forms after vision was gained; a long, gradual, learning process was necessary to enable the patients to perceive. There are, however, serious deficiencies in this evidence (cf. Michael Wertheimer, who describes some of the flaws and, in addition, observes that von Senden has often been cited erroneously). The conditions and the exact time after operation of the observations were not adequately described; the extent of vision present before operation varied from case to case; some of the cases were young children whose reports are difficult to evaluate. Moreover, the patients, after operation, were faced with a strange new world and often the investigator (usually the surgeon) did not know what questions to ask, or what tests to perform, in order to elicit the subject's experience. In one case, for example, the patient "had great difficulty in describing her sensations in such a way as to convey any clear conception of them to another." Much of this evidence, therefore, is inconclusive.

This discussion is concerned primarily with the effect of early learning on later learning where actual skills are involved.

The question of the learning of emotional and dependent behaviour is more complicated and there is less available evidence with human beings.

What evidence there is suggests that isolation of a physical kind can be extremely disturbing. For example, the widely known work on adult isolation at the laboratories which has been reported by Bexton, Heron and Scott (1954) suggests that, "in other words, the maintenance of normal, intelligent, adaptive behaviour probably requires a continually varied sensory input. The brain is not like a calculating machine operated by an electric motor which is able to respond at once to specific cues after lying idle indefinitely. Instead, it is like one that must be kept warmed up and working," and that, in summary, this kind of deprivation resulted in "changes in intelligence-test performance and the hallucinatory activity,

induced merely by limiting the variability of sensory input, providing direct evidence of a kind of dependence on the environment that has not been previously recognized."

The field is poorly developed, however, and has mostly centred around studies such as those of Spitz (1945, 1946, 1955) which are dealt with in detail in the section concerning maternal deprivation. It is interesting to observe that critics such as Pinneau (1955) draw attention to the conditions under which the children in Spitz's study lived. Not only were they deprived of the continuous attention of one mother, but in addition, by reason of staff shortage and because of physical isolation from one another, the children were actually prevented from exploring their environments. The field deserves considerable further exploration. There would seem to be the key to a much more adequate approach to educational backwardness in some deprivation experiments, but more information is needed. Some of the Russian work reported in Smirnov's (1957) collection of essays points to an interesting new technique of training students who have been deprived of the experience of some essential technique in a basic subject, such as counting mentally in arithmetic. The technique is based on a slow and elaborate reconstruction of the elements of the technique and their eventual internalization in thought. Such a process both comes in to line with Hebb's theories of basic learning abilities, takes account of the important effects of deprivation and suggests a solution.

Any reader who finds difficulty in seeing the relevance of these observations has only to consider the very common handicap of psychologists who lack adequate statistical and methodological training. The difficulties and "backwardness" to which such a lack of training has given rise are responsible for many of our current theoretical disputes.

Observations on the Effectiveness of Treatment

It is curious that so little work has been done to evaluate the effectiveness of treatment for maladjusted children. In view of such findings as those of Curran (1937), Miles, Barrabee and Finesinger (1951), and Eysenck (1952) with adults it is an odd fact that fewer evaluations have been attempted in the much more difficult field of child care. One of the few available was presented at the N.A.M.H. Ninth Child Guidance Inter-Clinic Conference (1951). The results reported are based on follow-up data from twenty-seven clinics with added information from five more. There are many shortcomings in returns which at this time were heterogeneous and very variable in the descriptive categories used. In addition, they cover a number of different periods, including part of the pre-war depression in England as well as the war years.

Overall, of course, as the conference delegates were well aware, was the shadow of subjectivity of judgement. In one of the reports, however, this was overcome to such an extent that five judges showed diagnostic agreement to the extent of intercorrelations of the order of 0.68 to 0.75.

The conference consisted of speeches and reports from clinics. It is interesting to note that of the one hundred and fifty clinics asked to co-operate, only thirty-four replied and submitted data although lack of time to compile data is given as the explanation for the small number of returns. The data presented by twenty-seven clinics enabled analysis by type of problem referred, diagnosis, cause of maladjustment ascribed and assessment of follow-up. The results from twenty clinics were summarized and cover 1,530 minors, 501 being girls and 1,029 boys, all between one year and 19 years of age. The type of problems noted were 462 behaviour problems, 262 psychosomatic cases, 370 personality problems, 247 educational problems and 36 unclassified cases. Diagnoses could not be tabulated because not all clinics replied and terminology differed considerably. Treatment, however, could be divided into five categories—

Play or psychotherapy	702
Parent guidance	592
Environmental adjustment	228
Remedial teaching	143
Group therapy	57

At the time cases were closed 895 cases were accounted for with 491 improved or symptom free, 64 improved and recovered, 172 unchanged or slightly worse and 14 unchanged or slightly better. The rest were accounted for in various ways irrelevant to the present discussion. The figures for recovery are impressive, but there is no way of evaluating particular treatment for the data. Follow-up showed 358 cases with no symptoms, 225 with slight symptoms, 106 showing no change and 16 showing deterioration.

Some further information can be obtained by referring to the individual reports from regional centres. For example, the conclusions of one Birmingham study are illuminating and are best quoted fully—

(a) Results were better for children in the younger age groups, where habits and parental influences had not been operative for so long a period.

(b) The better results in children of average or superior intelligence already alluded to are confirmed in the following which shows that the improvement is more lasting and progressive than in those whose intelligence is below average or dull.

(c) The relation between good results and degree of co-operation from the parents is most revealing, e.g.

when co-operation was "good" the 90 per cent which were found improved at closure, had maintained the improvement on follow-up, whereas with "bad" co-operation only 48 per cent had improved at closure, and only 66 per cent had maintained it.

(d) The children referred for "nervous" disorders are more likely on the whole to respond better, and these are really the more important cases, as the behaviour problems are more likely to be "grown out of" or yield to external circumstances, such as a change of environment.

Many other impressions emerge from the data presented, but it is doubtful whether any more definite conclusions could be sustained on the basis of the figures available because referral characteristics varied from region to region. Another chapter in this volume has been devoted to a more complete evaluation of treatment and those interested will find there a fuller analysis of the method used.

The Psychology of the Abnormal Child

It has not been possible to present a very detailed exposition of the psychology of the abnormal child in this chapter. Notably, discussion of delinquency and mental deficiency has been excluded and insufficient attention has been paid to fantasy fears and dreams. The authors believe, however, with these exceptions, that they have reflected the pre-occupations of child psychologists interested in abnormality.

There is no question that psychologists and psychiatrists in the last twenty years have been very much concerned with Freudian hypotheses about the later effects of early childhood experience. There is also little question that Mayer-Gross, Slater and Roth (1954) are correct when they point out that: "The hope of preventing, on a large scale, the psychological and social failures of adults by the psychiatric treatment of children, may well prove illusory; there are no present grounds other than optimism for thinking otherwise."

As was demonstrated in the early part of this chapter, the definition of maladjustment in children is not readily made. Symptoms which remain and refuse to yield to treatment are often minor deviations in an otherwise normal behaviour at a later stage of development. Similarly, acute maladjustment can disappear in children as readily as neurosis in an adult, and here as there, whether treated or not. Definition is just not so precise. It might be wise therefore to consider childhood maladjustment, either from the point of view of symptoms, or in completely different diagnostic groups from those applying to adults dependent on developmental arrest rather than by syndromes. The evanescent character of presenting symptoms as indicated by Thorpe and James (1957) makes diagnosis even more unreliable in the case of

childhood neurosis than it is with neurosis in adults. In addition, the likelihood is great that the effect of one stage of development on another is less than has been claimed, as Orlansky (1949), Beach and Jaynes (1954) and, recently, Beloff (1957) have indicated.

Psychosis, except where defined as in the case of schizophrenia by Mayer Gross, Slater and Roth (1954), namely in terms of the symptoms of schizophrenia in adults, is just as difficult to define. So far the Registrar General's report for 1955 shows an admission rate for schizophrenia within the age group 10-15 years of 22 per million Home Population for males and 23 per million for females. This compares, for example, with 746 per million for men between the ages of 20 and 24, the highest figure, 23 per million, for men in the age group over 65 is the only other rate (except that for the over 75s) which is not double this expectation. The average figure for all ages is 260 per million for men and 232 for women. This reflects the tendency of psychiatrists not to diagnose schizophrenia before puberty and is part of the confusion on this point which may account for the inconclusive nature of the discussion in the symposium quoted earlier (Kanner, 1954).

Psychopathy, which has not been discussed in this chapter, has been no better defined by psychologists than psychiatrists. Psychiatrists such as Curran and Guttman (1949) recognize a number of definitions of psychopathy and the recent report of the Royal Commission on the law relating to Mental Illness and Mental Deficiency (1957) succeeds only in reaffirming the present definition of the moral defective, calling this kind of person a psychopath and extending the definition to those with higher intelligence quotients. It is further suggested that the psychopathic personality is either aggressive or inadequate. So far most psychologists have not recognized the "inadequate" psychopath and definitions such as those offered by Eysenck (1957) classify psychopaths as extraverted neurotics with characteristically slow conditioning, poor persistence and a "tough minded" attitude. Eysenck's view is that the confusion of psychopathic definition can be resolved by considering the psychopath's social failure and inferring from this and his low conditionability, that the psychopath, like the hysteric, fails to learn readily. This accounts for his lack of moral and social standards. The dysthymic, on the other hand, conditions too readily. This theory is related to Mowrer's (1950) two-factor theory of learning and refers to autonomic "learning." The theory is discussed fully elsewhere, but, essentially, social conditioning is supposed to depend on autonomic conditioning, and this is supposed to be deficient in psychopaths. By definition, therefore, psychopathy cannot occur or be recognized until social conditioning has failed. It is therefore a condition which is likely

to have a late onset. The Registrar General's Report (1955) notices twelve cases per million population for boys between 10 and 15 and eight per million for girls.

This kind of definition does not make the distinction made in the Royal Commission Report between inadequate and aggressive psychopaths. This is only one of many differences of definition, and hence of incidence, which have been noted by psychiatrists. At present aetiology is generally held to be unknown and definition is considered to be a matter of social convenience.

This confusion of definition in relation to neurosis, psychosis and psychopathy had left the field of childhood abnormality open to the extensive discussions of psychoanalytic theories of personality type referred to above. As we have emphasized, these suffer from a number of methodological weaknesses. Some of these have been already discussed, but one of considerable importance has not been mentioned. This is the need to control for genetic factors.

Methodologically, nearly all studies of child development neglect to control the genetic factor. This is scarcely surprising, as good control techniques would seem to be difficult to devise in the absence of a plethora of monozygotic twins reared apart, some according to strict, and some according to *laissez faire* disciplines. In a study such as that of Beloff (1957) but also in nearly all other studies, particularly those of Goldfarb (1943, 1945-6) the question of inheritance may play a part. Bodman (1950) referred to this possibility in his discussion of constitutional factors in hospitalized children. He tried to match children in two groups, according to parental history, for the disorder under study. This technique, whilst imperfect, is better than ignoring one important variable.

However, just as the Mill Hill studies during the last war revealed constitutional disposition to neurotic breakdown (Slater and Slater, 1944), they also showed, as did First World War experience, that neurotic breakdown could result from situational stress. This is just as likely to be true of children as adults. The possible error made by some workers, especially the analytically oriented, has been to regard environmental or training conditions during childhood as prognostic of later breakdown. If, however, we regard them as important for the child at the time, we can see that children's emotional disturbances might be studied as forms of reactions to situational stress irrespective of predisposing constitution. This short-term approach has not been investigated, because of the preoccupation with long-term hypotheses and also because of the findings of twin studies such as those of Eysenck and Prell (1951), which suggested that a high percentage of neurosis is inherited. However, the incidence of neurosis does increase during wars, and

neurosis has been shown to clear up even independently of treatment (Eysenck, 1952). In children, where the symptoms of neuroses are even less enduring than with adults, it would seem to the authors that further studies should be made by psychologists of situational stress in relationship to childhood maladjustment. It goes without saying that these should be controlled for parental histories.

It is true that in the field, situational factors are often presumed and thought to be too obvious to investigate. However, investigations of such obvious "facts" as the adverse effects of maternal deprivation are unusually difficult to prove. A possible reason for this is that, because of the complexity of environmental forces impinging on the individual, effects powerful at one stage may be combated by more powerful and irrelevant or opposite forces at the next. Whatever the cause, it seems desirable at this stage to examine the epidemiology of childhood maladjustment in an effort to elicit the extent to which such maladjustments are a social problem. This is likely to be a rewarding line of study because the incidence of severe psychotic disorders in children is known to be low and because the majority of maladjustments such as instability or neurosis are likely to be as transitory as they are in adults. For these reasons, irrespective of the aetiology of individual predispositions to breakdown, actual breakdown may be very much an end product of multiple factors of social stress. If we neglect the long-term effects of such factors and study them in their immediate results, we may make some advances on the interesting beginnings, now long past history, of Faris and Dunham (1939). At present, the clinic and the laboratory are separated by too great a gap. The possibility of closing this gap depends in part on enlarging the concept of maladjustment by a sociological study of behaviour. In part also, it depends on the developments of work like that of Miller and Dollard (1941), Mowrer (1950), and Eysenck (1957), which attempts to link laboratory learning theory with social learning, failure to learn and overlearning. Anthony (1957), Hindley (1957) and Gewirtz (1957) have recently attempted to integrate the work in this field. The attempt which has already been made to study parent-child relations will clearly continue, possibly influenced by learning theory. At present it is informed by an unfortunate mixture of basic Freudian theory and common-sense observations. The result is that its hypotheses are too vague to be verified by any experiment which has yet been devised. To get beyond this point the field must be critically reanalysed.

CHAPTER 11

Somatic Reactivity

IRENE MARTIN

THIS chapter will be concerned with experimental data on certain autonomic functions and on skeletal muscle activity assessed by recording muscle action potentials; these two classes together will be termed "somatic responses." Almost all these physiological variables are highly complex processes, requiring a degree of care in matters of instrumentation, controls, procedure, recording and measurement, rarely found in psychological experiments. It seems, moreover, to be curiously true that the more ambitious and complicated the project—and it is ambitious indeed to hope to establish the peripheral somatic concomitants of certain inner "feelings"—the more studied the neglect of a rigorous experimental technique.

Responses of this kind are obviously associated with many of the overt activities observed in the individual, but they very frequently follow many kinds of stimuli even when no movement is apparent. It is proposed to deal briefly in this chapter with the course of autonomic and skeletal muscle activity during the performance of particular tasks, and some evidence will be presented to show that the underlying physiological state is, as would be expected, of great importance in determining certain aspects of performance. The main concern will be, however, with the somatic responses of the resting individual when stimulated by controlled sensory stimuli to which he is required to make either no overt response or simple verbal responses.

There would appear to be every justification for first studying somatic responses under the simplest experimental conditions, since one of the fundamental tasks of an experimental approach to behaviour (and one which has received surprisingly little attention) would seem to be the determination of characteristic curves of responses as functions of input variation. Only in this way does it seem possible to understand the nature of the responses, their interrelations, and their functions under varying experimental conditions,

on all of which could be based a systematic interlocking of facts.

This policy has not been explicitly stated in experimental work carried out within this field, with the notable exception of R. C. Davis, whose careful work well illustrates this outlook. Important, too, are the recent suggestions of Malmö (1958) linking physiological type measurements with learning theory. But the general approach in psychophysiological research has been confused and unformulated. Some specific guidance is urgently required to direct research in this field, and it will be argued in this chapter that one of the most fundamental ways of understanding human behaviour and its abnormalities will be via knowledge of the essential functions of the central nervous system.

Few of the hypotheses which have been mentioned in the literature merit really detailed comment (many of them appear to be ingenious and stimulating but are only loosely related to the specific experiments they purport to guide) but those which have been more persistently treated—Cannon's emergency arousal, and autonomic balance, for example—will be dealt with.

Most important, it is highly necessary to mention the real problems of recording responses: instrumentation, variables affecting the response, type of measurement to be made, etc. The data at present available can best be organized on the basis of the variables themselves—skin resistance, blood-pressure, peripheral vasomotor activity, skin temperature, heart rate, pupillary reactions, respiratory activity, and muscle action potentials—and the interrelation of these under some conditions will be considered in the following pages. So far as it is possible an attempt will be made within the individual sections to classify the available studies in accordance with response characteristics, i.e. into adaptation effects, varying amplitudes and latencies of response to different intensities of stimuli, and changing patterns of response. No

complete consistency of this kind of classification is possible since, for some functions, such data have not been obtained; where this is the case an overall review of the available literature will be presented instead. The important function of conditioning, about which there is so much experimental evidence, will be treated fully in a separate chapter.

The present stage of development of research into somatic responses is such that it is still necessary to consider the usefulness of such topics as "emotion," within which a great part of the research using physiological measurements has been carried out. Psychologists in the past have been preoccupied with traditional categories of behaviour—instincts, emotions, motivation, and so on—which, in spite of the many objections to them, have been retained (sometimes redefined) and are in current use. Their reinstatement has frequently been accomplished simply by linking them to postulated physiological states; as Davis (1953) has commented, too often there has been simply a "physicalizing" of old concepts. The question to ask is: do concepts like motivation and emotion (with subcategories of anxiety, depression, etc.) provide a classificatory system within which to place the factual data obtained from objective measurements of physiological activity in human behaviour? The problem has particular relevance to studies of psychiatric patients, where emphasis is placed on emotional states such as anxiety. In view of the fact that our understanding of terms such as anxiety is largely derived from experimental analysis, the usefulness of introspective evidence will be considered first.

INTROSPECTIVE EVIDENCE

The simple reality of our experience is so evident to us that it is frequently argued that no complete account of emotion can ever be given without reference to private data. In a sense, of course, this is true, and it depends mostly upon personal views and aims whether such data are considered useful or not at the present.

The extensive and *wholly* introspective analysis by early psychologists was of little value: it led to no sound measurement, classification, or theoretical development. Yet introspective data of a sort continue to be used in many psychiatric studies where patients' judgements form the basis of clinical attempts to "objectify" symptoms. The interesting work of Shagass and Naiman (1956) on the sedation thresholds of different groups of psychiatric patients, might illustrate the type of clinical investigation which attempts to objectify clinical assessments of anxiety or tension, and Malmo and Shagass's work (1949*b*) the attempt to relate physiological activity of certain areas to subjects' complaints of symptoms. In contrast, many psychologists have despaired of attempts

to establish homologies between precise physiological events and vague and ill-defined emotional states assessed clinically or introspectively, and it has been argued that, if the concept of emotion is to be retained at all, it must be as a scientific inference rather than as a reality of experience (Brown and Farber, 1951). The experimental study of "anxiety" can possibly be made on this basis, but it is so far only a guess that specific responses defined operationally will relate to the anxiety constellation in clinical use.

A glance at the literature demonstrates that it is the different types of introspective evidence used which have led to confusion and argument about its value. Simple judgements—of intensity of sensory stimuli, or location of muscular aches—may form a useful basis for further experimentation, but the complex introspective analysis of higher mental activities seems to lend itself less readily to experimental control. It is predominantly this latter type of evidence which is used in psychiatric studies and which, coupled with clinical observation, has led to the development of a number of rather general hypotheses about the behaviour of psychiatric groups.

Hypotheses from such sources are necessarily couched in somewhat general terms, and offer little guidance when applied to specific experimental problems (cf. theories of autonomic balance and Cannon's emergency arousal discussed below). Not only is the classification of subjects in doubt, but so many different response measurements and stimulus conditions have been used that any integration or evaluation of the findings is (until they are repeated) both difficult and of doubtful value.

There remain a few careful, and some not so careful but interesting, experiments which will be described. The criticism which can be levelled against many of these is their lack of structuring within a useful framework: it is small wonder that, with so few facts available, there is little close guidance from existing theories, but there is less excuse for the absence of narrower hypotheses or aims to direct research towards a better understanding of these omnipresent psychophysiological functions.

The viewpoint, reached after considering the psychological literature, is that a detailed description of these somatic responses in relation to simple, quantified stimuli should lead towards a better description of the curves of basic processes, such as adaptation, and that the study of these response curves in relation to abnormal conditions (drug effects, for example) should prove more fruitful than the study of arbitrary measurements of responses to complex situations which cannot easily be brought within experimental control. Unfortunately, the desirability of objectivity and reproducibility of data,

as well as of the quantification of stimuli, has not always been explicitly recognized in this field.

The measurement of "emotion" has frequently been attempted by means of physiological responses, and a glance at its status in psychology provides a useful starting point for considering research into autonomic and skeletal activities.

EXPERIMENTAL DEVELOPMENTS

From the early days of psychology a basis for the objective study of emotions was discerned in autonomic responses (*see*, for example, James, 1902). In Cannon's classical work with cats (1920) the importance of autonomic reactions in supporting muscular activity in states of defence and attack was clearly described, and terms such as fear and anger were applied to a class of behaviour fairly well defined, although not explicitly so, in stimulus-response terms.

In addition to the downward discharge from the thalamus, activating the sympathetic nervous system, Cannon pointed to the upward discharge from thalamus to cortex, which he supposed added the familiar emotional tone to incoming sensory impulses and reduced the inhibitory action of the cortex. Later research has tended on the whole to support and elaborate Cannon's thalamic theory. (Lengthier discussions may be found in Arnold, 1955; Gellhorn, 1953; and Lindsley, 1951.)

As is well known, Cannon's work with cats dealt with the usefulness of bodily changes as emergency functions, for example, the utility of the increased blood sugar as a source of muscular energy, of vascular changes favouring muscular exertion, of rapid coagulation in preventing loss of blood. In particular he laid stress upon reactions in states of fear and anger (considered to be dominant emotions) in which sympathetic nervous discharge was *diffuse*, involving acceleration of the heart, contraction of the arterioles, dilatation of the bronchioles, increase of blood sugar and sweating, inhibition of activity of the digestive glands and of gastro-intestinal peristalsis. On the other hand, Cannon believed that in conditions of thirst and hunger the general bodily need is signalled by more well-defined localized sensations, and so he drew a distinction between the appetitive and emergency functions of the autonomic nervous system.

The description of the emergency reaction appealed to psychologists, and Freeman's approach (1948) illustrates how Cannon's concepts were enthusiastically applied to the study of human behaviour. This writer advanced the thesis that all behaviour is an attempt to preserve organismic integrity by "homeostatic" restorations of equilibrium, and proposed a study of the typical homeostatic response curve from

a basic energy level (relaxation) when the subject is "displaced" by an external stimulus of controlled intensity and duration. "The equilibratory sequence has three phases: (i) mobilization, wherein bodily energies are internally aroused to meet the stimulus-induced displacement; (ii) discharge, wherein the aroused energies are externally expressed by overt responses, and (iii) recovery, wherein the organismic energy system returns towards its pre-stimulus condition." Freeman believed that the major parameters whose interaction determines the personality pattern were discoverable through measurement of physiological reactions to common disturbing stimuli such as the noise of a pistol shot and frustration tests.

There followed a period of fairly intensive analysis of autonomic responses and their interrelations, leading to the description of many new facts, this, in turn, led to a modification of the original simpler viewpoint on autonomic functioning. Many years of research have followed Cannon's theory, and some of the subsequent physiological studies of subcortical mechanisms, such as the diencephalon, which have considerably enlarged our understanding of the higher-level organization of the autonomic nervous system, will be mentioned in the following sections.

The well-argued paper by Brown and Farber (1951) has recently discussed afresh the problem of emotion. They advocate that emotions can be most profitably conceptualized as hypothetical variables intervening between environmental conditions and responses, and that this should lead to "guesses at laws" concerning the functional relations between the hypothetical emotions and observable behaviour. "These guessed-at-laws would be of the general form 'behaviour is such and such a function of emotion or emotions'." Antecedent events, both external and internal, must be described, and any proposed theory must contain coherent statements of its relationship to the constructs contained in more general theories of behaviour. Brown and Farber illustrate this approach with anxiety and frustration. Anxiety, for example, is defined as the conditioned form of the pain-fear response (Mowrer, 1950) and it is widely assumed in learning experiments that the response involves autonomic arousal and skeletal motor discharge. (Mowrer, 1950; Solomon and Wynne, 1954.) This is a legitimate and potentially useful definition, but parametric studies of this state in man are still lacking.

Several psychologists, also rejecting the traditional concept of emotion, have argued that behaviour subsumed under this heading be placed along a continuum of energy mobilization (Duffy, 1951) or activation (Lindsley, 1951; Schlosberg, 1954). Various indices for assessing degree of arousal have been proposed, and Malmö (1957) has discussed the

possible relationship between the intensity continuum and experimental investigations into anxiety and motivation.

There is a very great difference in outlook between the earlier psychophysiological research which concentrated on measuring "emotion" in its various forms, and the modern tendency to dismiss such concepts and to develop the usefulness of psychophysiological measurement within broader systems, such as the arousal continuum and learning theory (see Arnold (1955) for a recent survey of theories along traditional lines, and Malmö (1958) for newer proposals in relation to learning theory).

The task in hand is to determine in what sense the available data have laid the foundation of a systematic

treatment of "emotions" and whether they have advanced our understanding of autonomic and skeletal muscle functions *per se*. The following sections will deal with experimental work on somatic responses first treated rather generally, and then more specifically considering the separate variables such as skin resistance and muscle action potentials.

A fairly wide cross-section of experimental studies will be reported since the field is not dominated by highly formulated aims and methods; unfortunately, very few studies have been repeated, so that a selection criterion of reproducibility of results can hardly be upheld. Discussion will be restricted to those studies where reasonably well-defined stimulus and response measures have been employed.

THE AUTONOMIC NERVOUS SYSTEM

Autonomic Balance

An early view on autonomic balance put forward by Eppinger and Hess (1910) has engaged the interest of many psychologists, who have made frequent attempts to measure autonomic balance, and to establish its personality correlates. Among the most serious and thorough investigations are those of Wenger (1941, 1948) who, differentiating on a chemical (i.e. adrenergic-cholinergic) rather than anatomical (sympathetic-parasympathetic) basis, aimed to test the hypothesis that autonomic imbalance, when measured in an unselected population, would be distributed continuously about a central tendency which he defines as autonomic balance.

A large-scale study (1948) was carried out upon aircrews during the war; it followed earlier work with children which had delineated a factor described in terms of a number of functions innervated by the autonomic nervous system and a second factor of muscular tension, and it seemed likely that these two factors might be of use in the elimination of unpromising men from the Army Air Force.

Careful preliminary investigations were made into effects of uncontrolled variables such as humidity and time of day, into the effects of different test administrators and methods of recording (e.g. different electrode jellies on skin conductance). Reliability coefficients were obtained for each test (see Table XI.1).

The 1948 monograph describes several studies, the results of which can briefly be summarized as follows—

1. a picture of sympathetic imbalance was found in the sample of operational fatigue patients, and the results were believed to support the contention that operational fatigue is characterized by excessive activity of the sympathetic branch of the autonomic nervous system.

2. from the second study it was concluded that autonomic imbalance in psychoneurotic patients, with functional predominance of the sympathetic nervous system, was indicated. The combined psychoneurosis test syndrome was seen to be similar to, but not identical with, that reported for operational fatigue.

TABLE XI.1
MEANS AND STANDARD DEVIATIONS OF NORMATIVE SAMPLE FOR ALL TEST VARIABLES AND TEST-RETEST RELIABILITY COEFFICIENTS FOR TWO SAMPLES

(From Wenger, 1948)

No.	Variables	Mean (N = 488)	σ_{488}	r_{34}	r_{39}
10	Salivary output	4.2 cc	1.7	0.88	0.85
12	Salivary pH	7.2 pH	0.4	0.47	0.62
13	Dermographia latency	13.3 sec.	4.5	0.35	0.42
14	Dermographia persistence	16.8 min	9.2	0.63	0.19
15	Palmar conductance	16.8 μ mhos	7.1	0.70*	0.57
17	Log conductance change	30.1 log units	13.7	0.65*	0.70
19	Volar conductance	7.3 μ mhos	2.2	0.67	0.27
21	Systolic blood-pressure	111.1 mm Hg	9.0	0.74*	0.33
23	Diastolic blood-pressure	70.0 mm Hg	7.4	0.67	0.33
25	Pulse pressure	41.1 mm Hg	10.0	0.64	0.44
27	Sinus arrhythmia	0.7 rating unit	1.1	0.25	0.45
28	Heart period	160.4 millimin/ 10 periods	23.5	0.73*	0.66
30	Sublingual temperature	99.0°F	0.4	0.11	0.28
32	Finger temperature (1st)	34.9°C	1.9	0.51	0.73
34	Finger temperature (2nd)	35.4°C	1.4	0.55	0.27
36	Lymphocytes	35.6 per cent	8.4	0.30	0.48
38	White blood count	7,500 per cu mm	1,680	0.36	0.05
39	Eosinophils	1.3 per cent	1.9	0.25	0.09
40	Blood sugar	94.0 mg/100 cc	18.0	0.22*	0.11
42	Respiration period	5.1 sec	1.4	0.65	0.68
44	Tidal air mean	21.8 mm	7.0	0.53	0.38
46	Tidal air sigma	4.5 mm	2.8	0.64	0.28
48	Oxygen consumption	50.4 cal per hr/ sq m	8.3	0.57*	0.10
50	Weight/Height	4.6 (10 step scale)	2.1		
51	Relaxation rating	5.1 rating units	1.4		
52	Pupillary diameter	5.3 mm	0.9	0.71	0.64

* Measurement influenced by the effect of a post-absorptive resting state.

3. Conclusions from separate investigations of asthmatic and peptic-ulcer patients were the same, in so far as no support was found for the hypothesis that these disorders are related to parasympathetic predominance as measured by the tests.

A factor which was satisfactorily defined as an autonomic factor arose from the analysis of the physiological data. This factor did not correlate to any extent with personality traits measured by Guilford's S.T.D.C.R. and G.A.M.I.N. scales (see, however, Eysenck, *The Structure of Human Personality*, p. 196, 1953, for a discussion of these results). Another factor was identified as "muscular tension," although it was less clearly defined.

Other attempts have been made to investigate autonomic balance (Darling and Darrow, 1938; Darling, 1940) all these attempts, however, carry the assumption that both sympathetic and parasympathetic systems act as a whole and in a generalized fashion, an assumption which has been amply criticized.¹ Darrow (1943) has pointed out that it is often difficult to determine whether an apparent change in the autonomic nervous system is due to increase of activity in one branch of the autonomic system, or to decrease of activity in the other. As he put it, the problem is literally to determine the weight on either side of a "balance," when that on neither side is known.

Some of the autonomic functions, such as sweat glands and peripheral blood vessels, used in early attempts to establish autonomic imbalance, were mistakenly believed to be innervated by both sympathetic and parasympathetic nerves. Autonomic innervation, either sympathetic or parasympathetic, of other variables is not proven; for example, Rothman (1945) argues that the phenomenon of red dermographism is a local response of the contractile elements of small vessels, not due to autonomic reactivity since it can be elicited in completely denervated areas with the same intensity as in normal innervated skin.

Even those organs with a clearly dual supply of parasympathetic and sympathetic nerves reveal, upon further study, a complex kind of innervation. Lacey (1956) cites an experiment in which the following simultaneous stimuli were applied to the peripheral cut ends of the appropriate nerves: a sympathetic stimulus, capable of increasing heart rate by 41 beats per minute, and a vagal stimulus capable of decreasing the heart rate by 34 beats per minute. The net result was a decrease of 30 beats per minute, illustrating the

importance of vagal tonus. Moreover, it is known that sympathetic excitation *potentiates* vagal inhibition: "thus, simultaneous stimulation of the cardiac-accelerator nerves or small doses of epinephrine makes the heart *even more sensitive to vagal stimulation*." (Lacey, 1956.)

Such facts as these inevitably lead to caution in interpreting the results of experimental work which has been carried out on the concept of sympathetico-tonia. At first glance it might be thought that a technique such as factor analysis could be of value in this field. But, as Darrow (1943) comments on Wenger's work, although factorial analysis may reveal relationships which otherwise might escape attention, it cannot "impart autonomic significance to tests which are not themselves valid according to acceptable physiological criteria."

Attempts to measure sympathetico- or vago-tonia of the autonomic nervous system by means of the reactions of the circulation to certain drugs have been attacked by Altschule (1953): "when the tests are carried out as described . . . they do not measure the reactivity of the autonomic nervous system. What they do measure are: the activity of enzymes that inactivate or destroy the drugs; the reactivity of the end organs (the heart and the blood vessels); and, in the case of acetyl-choline, the reactivity of some autonomic ganglia. All these phenomena occur at the same time, and any conclusion concerning the activities of the autonomic nervous system as a whole during the test is invalid."

Many years of investigations into autonomic functions have followed the publication of the Eppinger and Hess theory, and the need to modify the original conception of autonomic functioning is now widely recognized. Hess (1954) has stressed that classificatory terms having a *functional* significance are more appropriate than a separation based on morphologic criteria, such as the separation into sympathetic and parasympathetic systems: "this functional interpretation involves recognition of the fact that the antagonism between the sympathetic and parasympathetic systems really enables these two components to *supplement* each other in their effects."

Recent experimental work has also shown that, in arousal, individuals excite preferred organs rather consistently, and the type of organ or pattern aroused may differ from individual to individual. Lacey and his associates (1952, 1953) have carried out a series of investigations into differences in somatic response patterns to stress. A group of children in one study (1952) and adults in another (1953) were subjected to various stresses—mental arithmetic, hyperventilation, letter association, and a cold pressor test. Physiological variables recorded were (from children)

¹ It should be added that Wenger (1957) has recently described a modified approach to the problem of autonomic balance, based on fewer variables and aiming to differentiate hypo- and hyper-sympathetic or parasympathetic *syndromes*.

blood-pressure, heart rate, heart-rate variability and palmar conductance, and (from adults) heart rate, heart-rate variability and palmar conductance. They found that the patterns were fairly reproducible upon immediate retest, and in certain cases remained consistent for long periods. They also emphasized that patterning may appear in very similar functions, for example within cardiovascular variables themselves, as well as between say, the cardiovascular and sudomotor systems.

These authors take the view that the question "how reactive is this individual?" is not one that can be asked with respect to the autonomic system as a whole. For one measure he may be a marked hyporeactor, for another a marked hyperreactor. To determine the function showing truly maximal activation in a given individual would require simultaneous measurement of all autonomic functions, a task obviously impossible at present. They have formulated a principle of relative response specificity which states: "some individuals are so constituted that they will respond to a given hierarchy of autonomic activation whatever the stress: others will show greater fluctuation from stress to stress although they will exhibit one pattern more frequently than another; still other individuals will randomly exhibit now one pattern, now another. In addition, although the rank order of reactivity remains the same from stress to stress, the quantitative differences between the degree of activation of the different physiological measures will fluctuate considerably" (Lacey *et al.*, 1953).

Malmö and Shagass (1949b) measuring autonomic and skeletal muscle functions in patient groups have postulated an allied principle of symptom specificity. They found that cardiac patients responded to stress with acceleration of heart activity, hypertensives by rise in blood-pressure, and that people with headache complaints had a higher level of muscle activity in the forehead than those without headaches. From these data it was hypothesized that "stress" situations do not activate all physiological systems, but only the specific physiological mechanism underlying the somatic complaint. Both these principles of specificity of response and symptom specificity, which seem to be reasonably well established under certain stimulus conditions are, of course, in disagreement with the concept of "mass action" of the sympathetic division of the A.N.S.

AUTONOMIC AND SKELETAL MUSCLE SYSTEMS

Freeman (in *The Energetics of Human Behaviour*, p. 261, 1948) has argued for the study of the relation of overt motor discharge to autonomic arousal processes during experimentally induced frustrations, on the basis of some preliminary studies which suggested that individuals who recover internal equi-

librium quickly show a high degree of externalized activity. He further drew attention to the *appropriateness* of the motor discharge in regaining equilibrium, quoting results which indicated that subjects who discharge relatively more of their aroused energies through the motor channel specifically appropriate to the experimental displacement, tend to recover equilibrium quickly and to be left with only small amounts of residual tension. Freeman has depended very heavily upon measures of skin resistance and G.S.R. to indicate the arousal and recovery aspects of responses; unfortunately the specificity in patterns of autonomic responses which has been demonstrated must lead to scepticism of results based on a single measure to represent general responsiveness. The results of Freeman's factor-analytic studies (describing factors of discharge control, drive arousal and discriminative capacity) and their relation to other factor analyses of physiological measurements have been discussed by Eysenck (1953).

The study of the interaction of skeletal muscle and autonomic functions is obviously of importance, and an attempt has been made to elucidate their relationship in learning and conditioning experiments, where both components may be present (Solomon and Wynne, 1954). The physiological levels at which interaction between the systems may take place has been surveyed by Kennard (1947).

It is commonly believed (following Cannon) that under some "emergency" conditions, autonomic functions are organized to support the efficient activity of the muscles for attack or flight; however, the greater speed of transmission of motor than autonomic nerves, the shorter latencies of muscular reactions and (in the absence of reinforcement of the motor responses) their more rapid extinction, are facts which argue against a necessarily "supportive" role of autonomic responses, at least under certain simple conditions (*see* Davis *et al.*, 1955, p. 21).

THE INHERITANCE OF AUTONOMIC FUNCTIONS

Jost and Sontag (1944) obtained measures of vasomotor persistence, salivary output, heart period, palmar and volar conductance, respiratory period and pulse pressure in groups of twins, siblings, and unrelated children. For these individual functions they derived difference scores between pairs of children (twins, siblings and unrelated). Only very small numbers of twins were seen, but some of the differences were significant, showing siblings to be less alike than twins, and unrelated children less alike than the siblings and the twins.

The inheritance in rats of certain elimination responses used as an index of "emotionality" is briefly discussed in Chapter 19 by Peter Broadhurst, and references given there.

ATTEMPTS TO DIFFERENTIATE EMOTIONS

The belief that separate emotions consist of particular patterns of autonomic and muscular responses has been widespread among psychologists, and several studies have been undertaken on this basis (Arnold, 1945, Ax, 1953). Such experiments involve complex stimulus conditions designed to arouse anger, fear, etc., or depend upon ratings of affective states or predominant needs, such as "anger out" or "anger in" (Funkenstein *et al.*, 1954). This means that their reproducibility is rather unlikely, and, in fact, the results of different experiments purporting to establish physiological concomitants of fear and anger have not in general confirmed one another (but see Funkenstein *et al.*, 1957).

It has been convincingly argued that the problem of

determining how many basic emotions "exist" is similar to that of determining whether any emotion "exists"—

More progress might have been made if it had been asked instead whether observable behavior is most satisfactorily explained by the introduction of one or more constructs carrying an emotional label. If it appears desirable to have more than one each must be shown to have relations that are in some way distinctive with reference to the other elements of the theory and to each other. Different emotions exist as realities for psychology only if different defining operations and interrelations can be clearly specified for them. If such specifications cannot be made the superfluous terms are scientifically inadmissible and must be coalesced or deleted; appeals for their continuance on intuitive or phenomenologic grounds must be rejected. (Brown and Farber, 1951.)

FUNCTIONS OF THE AUTONOMIC NERVOUS SYSTEM

Skin Resistances and the Galvanic Skin Response (G.S.R.)

Of all psychophysiological measures, changes in skin resistance (or its reciprocal, conductance) and the psychogalvanic skin reflex have become the most popular with psychologists. This is partly due to the simplicity of the instrumentation required, but largely to the extreme sensitivity of the G.S.R. to sensory and ideational stimuli.

There are two methods of recording: (i) the Féré phenomenon (the more commonly used) in which the passage of a small external d.c. current is used to obtain a measure of apparent resistance, and (ii) the Tarchanoff phenomenon, where no external current is used and the potential difference of the skin between the two electrodes is used to deflect a galvanometer. A close agreement of results from the two methods has been reported (Jeffress, 1928) although at least one very modest correlation (0.35, significant at the 0.05 level) has been recently reported (Terry, 1953). Slow changes in levels of skin resistance may occur during measurement; upon this slow baseline drift a quicker variation, lasting some seconds and termed the G.S.R., is observed to follow certain types of stimuli.

Changes in polarization and permeability of the tissues (sweat glands in particular) are believed to underlie both the Tarchanoff and Féré effects. The physical nature of the phenomena has been discussed by Landis (1932) and methodology and circuits by Davis (1930). Results of the Féré effect are generally reported in ohms resistance or mhos conductance; as James and Thouless (1926) pointed out, the resistance of the subject when measured with direct current from an external source of voltage may be termed an "apparent resistance." The amount is actually greater

than the subject's true resistance because of effects of the imposed E.M.F., and the E.M.F. of polarization; therefore unless the strength of the external current used, the characteristics of circuits, and area and composition of the electrodes are held constant from study to study, units of measurement from different experiments cannot be directly compared.

A method has been developed for the study of palmar sweating as such; this, a colorimetric technique, depends upon the interaction of a chemically treated paper with sweat containing a reactive salt, and the extent of the response can be graded according to the density of the stain (Silverman and Powell, 1944; see also Mowrer, 1953, for a further description of the technique and its application to the assessment of therapeutic treatment of psychiatric patients).

Wenger and Gilchrist (1948) obtained a correlation of 0.31 ($p < 0.01$), between palmar conductance and the stain index, although the palmar aspect of the fingers was used for the stain method, and the palm of the hand for conductance. They also obtained reliability coefficients of the two measures over different periods, and found that conductance measures were more reliable.

Factors which Affect Measurement

(i) *Electrodes.* This point is discussed by Landis (1932) and by Woodworth and Schlosberg (1954). Polarization, which may change either the voltage potentials or apparent resistance, may be reduced by the use of non-polarizing electrodes, for example, of silver-silver chloride, and by using a very small current. A detailed discussion of electrical phenomena within the skin and at the surface of electrode contact may be found in Rothman (1954).

The effect of the size of electrodes and cutaneous hydration on the electrical resistance of the skin has been investigated by Blank and Finesinger (1946) who found that the size of the electrode could be varied appreciably without changing the apparent skin resistance, as long as the area of skin moistened by the electrolyte solution was constant. As they pointed out, if an area of skin larger than the area of the electrode is accidentally wet with the electrolyte solution the apparent skin resistance will be low, and as the wet area outside the electrode dries the apparent skin resistance will increase. Any aqueous film such as sweat outside the area of the electrode but continuous with it acts to increase the size of the effective electrode.

(ii) *Temperature.* Kuno (1930) has argued that sweating caused by heating appears all over the body surface except the palms of the hands and soles of the feet. The effect of temperature on these regions has been investigated in several studies. No relationship was observed with basal resistance by Duffy and Lacey (1946) and Wenger (1948), but Conklin (1951) claimed positive findings and Venables (1955) found a sizeable relationship between temperature and conductance in a neurotic group above an effective temperature of 66 F, but not in a comparable normal group, a finding which S. B. G. Eysenck (1956) confirmed.

(iii) *Other factors.* The majority of studies has not established any relation between palmar resistance and humidity, although Venables (1955) obtained some evidence that humidity affects basal conductance level in both normal and neurotic groups.

Diurnal periodicity has been reported with resistance higher during the night than the day. Muscular tensions also influence the level of skin resistance (Freeman and Simpson, 1938; White, 1930; Wenger and Irwin, 1936). O'Connor and Venables (1956) have reported significant correlations between Binet I.Q. and resting conductance levels in imbeciles.

Measuring Units

The greatest complexity of handling skin resistance and G.S.R. results appears to lie in the treatment of measuring units. It is frequently stated that the magnitude of the response is related to the pre-stimulus level, i.e. the lower the degree of preceding activity the greater the response.

Lacey's article (1956) should be read on this topic. In general, the problem is to treat the raw data so that responses may be considered independently of basal readings, and so that scores yield a normal distribution. Some of the transformations in common use are the logarithm of the change in conductance, percentage conductance change, square root of conductance, and similar measures based on resistance units. New

scoring systems have been proposed, among them the Paintal index (Paintal, 1951) and the recovery quotient (Freeman, 1942), but, as Lacey says, many of these proposals have turned out to be specific to the original data and unsatisfactory when applied to newly-obtained data. S. B. G. Eysenck (1956) showed that different correlations between responses and basal scores may be found in different groups of subjects (normals, neurotics, psychotics).

The term basal level is, of course, used in several ways. Many experimenters allow a few minutes of rest in order to establish a relatively stable basal activity before introducing stimuli and the reading immediately prior to the stimulus is used to assess relations between response and base.

Lacey (1956) has protested against many of the attempts to derive "base-free" response scores. He argues that the proposed solutions have not been rooted in physiological fact or theory, but have emerged entirely as a result of statistical manipulations and contends that: "a basic physiological error is involved in the common practice of quantifying the reactions of autonomically innervated structures by computing algebraic or percentage changes, and that additional error is committed by seeking arbitrary mathematical transformations that irrationally (by which I mean empirically, and without regard to physiological theory) remove the dependence of such computed changes upon pre-stimulus levels of physiological functioning in a specific experimental situation. I propose that such procedures in effect ignore the basic fact that one of the main functions of the autonomic nervous system and associated endocrine glands is to maintain a homeostatic norm."

Lacey adds an important corollary to the principle of the homeostatic restraint of response, namely that: "the recorded autonomic response is a function both of the induced magnitude of autonomic activation (as it would be seen in the absence of contrary changes) and of the promptness and vigour of secondarily induced autonomic changes that serve to restrain and to limit the effects of the initial disturbance."

He feels that whatever statistical technique is employed it should not obscure physiological phenomena, and so goes on to discuss what can be done about the dependence of change upon initial level. He proposes that a rational procedure would be to establish norms, i.e. frequency distributions, of responses at varying pre-stimulus levels of functioning for varying populations and stresses. Since this is manifestly impossible he proposes that the best statistical approximation to this ideal solution is attained by use of the technique of regression analysis. This involves the analysis of regression of stress level on initial level, and the resulting scores he terms autonomic lability scores.

Psychophysiological Functions of Palmar Sweating

Kuno's opinion, mentioned earlier, is that sweating in man is not uniform over all the body surface, in respect of either actual secretion or physiological significance. Whereas general bodily sweating appears to be temperature regulatory, palms of the hands and soles of the feet do not conform to this general rule. Kuno found that sensory stimulation and mental stress are able to provoke sweating of these parts, and suggested that this sweating may have a functional use inasmuch as moistening the surfaces of the palms would increase the friction between them and the objects with which they come into contact, thus improving tactile acuity. Sweating is apparently more profuse on those parts of the palms and soles which are protuberant and likely to touch objects on grasping or on walking.

Darrow (1936) has also argued that the galvanic skin response is preparatory and facilitative. Thouless (1925) that resistance level reflects the preparedness of the organism to react, and Mundy-Castle and McKiever (1953) quote Biesheuvel as suggesting that it is the somatic concomitant of Pavlov's investigatory reflex. Many investigations have been carried out on the basis that changes in skin resistance form part of the emergency reaction of the sympathetic nervous system, and this measure has also been used to indicate arousal, activation (Schlosberg, 1954) and energy mobilization (Duffy, 1951). Such conceptions are strengthened by the high resistance levels found during sleep and the rapid drop in resistance observed upon awakening.

Experimental work on skin resistance and the G.S.R. to various stimuli will now be reviewed. It is obvious, from what has been said, that careful control of many factors must be exercised. In addition, the response is notoriously sensitive to irrelevant and uncontrollable details such as coughing, changes in breathing, shifts in position, and movement of the hands.

Adaptation

One of the main characteristics of the G.S.R. is the ease with which it adapts to repeated stimuli; this effect may be shown within a single session or from day to day. Changes in level of resistance have also been observed within the initial resting period which is generally allowed in most experiments, and it has been suggested that these reflect level of arousal, as, for example, when the subject becomes alerted or adapted to the general experimental procedure.

Auditory stimuli are usually employed in adaptation studies, but visual stimuli and electric shock have also been used. Unfortunately, some of the early studies, although well controlled, do not apply any statistical treatment to the data and it is difficult to

judge the significance of diminished responses when presented in graphical form.

An example is a study by Davis (1934) who studied finger-tip resistance of eight subjects over five consecutive days, and found that the size of the reactions, both to a ready signal and to the stimulus tone (a 1,000 cycle tuning oscillator sound) was progressively smaller from day to day. The absolute level of each day's curve was also higher than on preceding days, which suggested that reaction to the general situation (which must have had some stimulating value at first) also decreased, as did the reaction to the tone. It was noticed that reactions to mental work and to music were slower than reactions to noise and that the response to mental work remained constant throughout the five-day period (i.e. no adaptation) while the response to the music increased.

Thus the nature of the stimulus may be important in curves of adaptation and, as Coombs (1938) points out, some other relevant factors may be the duration of the stimulus and time intervals between stimuli. He investigated adaptation to various types of auditory stimulation—horn, knocker, buzzer and gong—and the influence of time intervals on adaptation. His conclusions were: (i) that adaptation takes place more rapidly with a fifteen-second interval than with a thirty-second interval between stimuli; (ii) that adaptation proceeds rapidly at first and then slows down, and (iii) that there was evidence of a transfer effect since adaptation to successive series of new stimuli proceeded more rapidly. Again, results were presented in graphical and tabular form, with no statistical treatment.

Adaptation of general level of palmar skin conductance during periods of response rather than to discrete stimuli was studied by Duffy and Lacey (1946). They found decreasing conductance during the course of a two-and-a-half-minute rest period preceding the stimuli, and during the four repetitions of an auditory discrimination task which were required in a single experimental session. Statistical treatment of the data showed that these falls in conductance were significant. Significant day-to-day adaptation effects were also observed during period of rest and auditory discrimination.

A recent study investigated the differential adaptation rates of normals, psychotics and neurotics during an initial rest period. Neurotics were significantly higher in resistance than normals at the first minute, but not at the sixth. A comparison of the groups was then made by an analysis of variance on the first five minutes' scores, and it was found that both the actual resistance levels and the slopes of the curves differentiated the groups: the psychotics maintained a higher *level* of resistance than normals, and the neurotics evidenced a slower *rate of change* in

resistance than normals during the five minutes (S. B. G. Eysenck, 1956).

It has been hypothesized that individual differences in G.S.R. adaptation rate may be related to temperamental factors underlying differences in excitatory-inhibitory balance. In a study based on this hypothesis the records obtained were classified into three groups according to the presence or absence of "endogenous" responses. The group with many

Decline in G.S.R. magnitude over ten repetitions (assessed by several statistical techniques) was found to be significant at the 0.03 level. Interestingly enough this decline in G.S.R. response occurred although basal resistance increased throughout the series of ten tones.

An increase in latency to repeated stimuli was noted, but it did not reach any adequate statistical significance level (*see* Table XI.2).

TABLE XI.2
SUMMARY OF RESULTS OF AN EXPERIMENT ON STIMULUS INTENSITY EFFECTS

(From Davis, Buchwald and Frankmann, 1955)

Variable	Response	Time (after stimulus of maximum response)	Stimulus intensity effect	Repetition effect	Differential effect of repetition
M.A.P (a-response)	Increase	1 sec	Significant	Decreases	Significant decrease for A* Non significant for B and C
(b-response) G.S.R.	Increase Decrease in resistance	3 sec (?) (Latency = 1.3 sec)	Significant Significant	Decreases Decreases	— —
G.S.R. latency			Significant	Increase	Significant decrease for A Significant increase for B and C
Breathing amplitude	Increase	15-20 sec for weaker stimuli	Significant for first presentation		Significant decrease for A Significant increase for B and C
Breathing cycle time	Increase	15-20 sec	Significant	Increase (Non significant)	
Pressure pulse	Decrease Increase	12.5-15 sec	Significant		Significant decrease for A Not for B or C
Volume pulse	Decrease	5-10 sec	Significant	Decrease (Non significant)	
Finger volume	Decrease	12.5-15 sec	Significant	Decrease (Non significant)	—
Chin volume	Increase	12.5 sec	Not significant	Decrease	
Pulse time	Decrease Increase	2.5-5 sec 7.5-10 sec	Significant	Decrease (Non significant)	—

* A = 120 db tone, B = 90 db tone, C = 70 db tone.

endogenous responses (the "labiles") tended not to adapt to the stimuli, whereas the group in whom G.S.R.s occurred only to the experimental stimuli (the "stables") did adapt (Mundy-Castle and McKiever, 1953). A subsequent study has also shown a very significant relationship between the frequency of "endogenous" (or spontaneous) responses and the ease of conditioning the G.S.R. (Martin, 1960). The significance of spontaneous autonomic responses has recently been discussed at length by Lacey and Lacey (1958).

A very thorough investigation of normal adaptation curves of skin resistance responses has been made by Davis, Buchwald and Frankmann (1955) using measures of G.S.R. magnitude and G.S.R. latency.

Stimulus Variation

The galvanic skin response can also be changed in amplitude by varying the intensity of the stimulus. Hovland and Riesen (1940) using both electric shock and auditory stimuli of varying intensities observed that galvanic reactions (Tarchanoff method) varied with the strength of shock stimuli in an approximately linear fashion, as did the logarithm of the response to intensity of tones (in decibels) except at extremely high intensities. A similar finding has been reported by Davis *et al.*, (1955) using db values of 70, 90, and 120, i.e. that the log response is a linear function of the acoustic pressure (*see* Fig. 11.6). In their study, repetition effects interacted with intensities of stimulation; there was a significant decline between first and

last presentation of the 120-db stimulus ($p < 0.01$) and for the 90-db stimulus ($p < 0.05$). For the 70-db stimulus the trends were in the same direction but did not reach statistical significance (*see* Table XI.3).

TABLE XI.3
MEAN MAGNITUDE (PER CENT) OF G.S.R. FOR
VARIOUS INTENSITIES OF A 1,000-CYCLE TONE
(From Davis, Buchwald and Frankmann, 1955)

Intensity	Quarter of sitting				Mean
	1st	2nd	3rd	4th	
120 db (A)	37.4	24.7	24.3	24.1	27.6
90 db (B)	14.8	9.3	8.0	3.2	8.8
70 db (C)	9.3	3.7	4.7	6.7	6.1
Mean	20.5	12.6	12.3	11.3	

Individual Differences

It can be readily appreciated that with so many variables and possible extraneous influence to take into account few studies carried out with the G.S.R. are likely to be entirely free from criticism. In addition, many personality studies have been carried out on small samples, often in a clinical context, and with no statistical treatment of results, so that evaluation of these is well-nigh impossible.

Landis summarized the available evidence in 1932, and drew attention then to the confused state of the findings concerning psychogalvanic activity in psychiatric patients, pointing out that there was no justification for using it as a measure of traditional psychological categories or personality traits. Since that time the topic has been vigorously pursued, and although additional results have hardly cleared the position a general impression appears to have emerged that schizophrenics frequently demonstrate high resistance levels and diminished responsiveness, while neurotics show a lowered resistance level and increased responsiveness. But it is doubtful whether any such general impression can be substantiated; what is urgently required is a careful specification of the stimulus conditions under which any discrepancy in physiological activity might be observed.

A very brief review of some recent findings will illustrate the present position. Freeman and Katzoff (1942) used a measure of G.S.R. recovery from different experimental frustrations which correlated with clinical ratings of emotional balance; Wenger's (1948) finding was that resting palmar conductance was significantly higher (i.e. lower resistance) in neurotic subjects and also that this measure was one

of the best indicators of improvement in patients after a period of convalescence. Both Malmo and Shagass (1949*a*) and S. B. G. Eysenck (1956) have, however, reported higher initial resistance levels in neurotic subjects.

Malmo and Shagass (1949*a*) found no significant differences between various groups of patients and normals, using several measurements of the G.S.R. to pain stimulation, and Paintal (1951) confirmed this on a psychotic group but observed differences in the response to threat of shock (psychotics showing lower responsiveness). Jurko, Jost and Hill (1952), measuring G.S.R. to the Rosenzweig Picture Frustration study, found no differences between controls and neurotics, but a lowered response in schizophrenics.

Higher initial resistance of schizophrenics has been reported by Malmo and Shagass (1949*a*) Jurko, Jost and Hill (1952) and S. B. G. Eysenck (1956). This last author found that not only initial and final resistances were significantly higher in schizophrenics than other groups, but that this higher level was maintained throughout the experimental session. She concluded that basal conductance was the best discriminatory measure between schizophrenics and normals, and that change scores tended to discriminate between groups only to the extent that they were themselves correlated with basal conductance.

Physiology of Skin Resistance and the G.S.R.

The sweat glands are innervated by the sympathetic division of the A.N.S. but are dependent upon cholinergic transmission at the end-organs. A very comprehensive review of the physiology of skin resistance was made by Landis in 1932, and more recently by McCleary (1950).

Measurements of palmar sweating are often advocated as relatively uncomplicated indicators of sympathetic activity, but Darrow (1943) has questioned this assumption pointing out that, because of their cholinergic mediation, conditions altering cholinergic activity, whether by the amount of available acetylcholine, the concentration of cholinesterase, or the presence of adrenalin, may limit the level of secretory activity and the magnitude of response to stimulation. Another point is that although there is a common tendency to combine observations on both skin resistance and the G.S.R. and to treat them as though they have a common basis, the possibility must be considered that the G.S.R. and basal resistance result from partly separate mechanisms.

The nature of the mechanism producing changes in skin resistance has been discussed by McCleary (1950). He summarizes three possible physiological bases of the G.S.R. and shows that evidence is more or less equivocal in all cases. These are: (i) a vascular theory, i.e. that vasodilatation causes the G.S.R.,

(ii) that secretory activity of the sweat glands gives rise to changes in resistance level, and (iii) that the phenomenon arises from involuntary muscular activity.

He favours the view that the galvanic skin response depends upon a change in the sweat glands that precedes actual secretion (*see also* Thomas and Korr, 1957, who have presented evidence that the relation of skin conductance to the number of active sweat glands is very nearly linear).

Extensive physiological studies of the G.S.R. have been carried out by Wang (1957, 1958), who has reviewed his own and other work in this field from the standpoint of reflex physiology; he draws the conclusion that there are a number of inhibitory and excitatory influences on the G.S.R. operating from different levels of the central nervous system.

Summary: Skin Resistance

1. *General conclusions.* The G.S.R. is dependent upon pre-change level of resistance; the usual response to a stimulus (sensory or "ideational") is a decrease in resistance.

Both level of skin resistance and the G.S.R. show effects of adaptation, the speed of which is partly related both to the intensity and modality of the stimulus used. Latency of the G.S.R. is between one to two seconds, and may increase slightly to repeated stimuli.

Skin resistance level is much increased during sleep, and is low during active, alert states. For this reason, it has been used as a measure of arousal. Sympathetic innervation of the sweat glands (via cholinergic mediation) is believed to underlie the phenomenon.

2. *In relation to psychiatric disorder.* Pre-stimulus (or rest) conditions: the findings are variable in neurotics, a group which may have the same or slightly higher resistance than normals (although there are reports of lower resistance). Schizophrenics' resistance is reported as being significantly higher than normal in a number of studies, and this high level may be maintained throughout the experimental session.

Changes in basal level during initial rest: neurotics appear to show less change than normals (this may mean less adaptation to the situation) but findings in schizophrenic groups are variable.

The conflicting findings concerning *reactivity* are probably due to the variety of stimuli employed. There is a little evidence that recovery may be delayed in certain patient groups, and that schizophrenics' reactions to sensory stimulation are similar to normals'.

Circulatory Functions

Cardiovascular variables accessible to measurement include peripheral resistance, arterial pressure (systolic and diastolic), heart rate and stroke volume. The

regulatory mechanisms and neural reflexes which operate to maintain homeostasis within the circulatory system have been well described in most physiology textbooks, as have some of the specific interactions between neural and hormonal effects.

Psychologists have been interested in the fact that cardiovascular responses take place in response to a wide range of stimuli including simple sensory stimuli and complex "emotional" situations and, as in the case of skin resistance, have supposed that measures of blood-pressure, heart rate, etc. may be related to certain psychiatric or psychological categories.

BLOOD-PRESSURE

There are many references in the literature to an increase of arterial pressure during emotional stress, but many of these consist of little more than uncontrolled observations, and only a few studies provide results which seem to be meaningful and which might be reproducible.

Factors which are believed to be responsible for the maintenance of blood-pressure are cardiac output, blood volume, peripheral resistance, and the elasticity of the arterial walls. Change of any one factor which might alter the pressure is generally offset by compensating mechanisms. Normally the peripheral resistance and cardiac output are adjusted so as to prevent any large change in mean arterial pressure, and failure to accomplish such an adjustment may in itself be indicative of arterial dysfunction (Hickam *et al.*, 1948).

Pressure declines from the aorta to the capillaries, and it is arterial pressure which has most often been investigated by psychologists; the average arterial pressure in man is given in physiology texts as about 120 mm Hg for systolic and 70-80 mm Hg for diastolic pressure. The difference between these two measurements is termed pulse pressure, and the arithmetic mean of systolic and diastolic pressure is called mean pressure.

Methods of Measurement

The commonest instrument for measuring systolic and diastolic blood-pressure is the standard mercury sphygmomanometer, but this instrument has many disadvantages; perhaps the most serious are the discomfort induced and the disturbance on the system being measured. Wenger (1948) also found that different examiners using this method obtained different mean readings for diastolic pressure.

Attempts have been made to produce continuous recorders which, to avoid the need for arterial punctures, employ a repetitive short-period occlusion cuff and usually record systolic pressure only. Such methods are of course indirect. Pickering (1955) has discussed some of the direct measures of arterial

pressure in man and the results of several studies comparing direct with indirect measurements. Errors of measurement varied from study to study, but on the whole were quite considerable.

Factors Affecting Blood-pressure ↙

Age, weight and the subject's sex may have an effect on blood-pressure. Systolic pressure seems to show some diurnal variation, being lowest during sleep (Kleitman, 1939) and highest at about 5 to 7 p.m. (Wenger, 1948, found it necessary to correct measures of systolic pressure against time of measurement). Arterial pressure may rise from distension of the bladder, and postural changes occasionally produce falls in pressure in some individuals. Blood-pressure readings may be influenced by variations in laboratory procedure and by different experimenters (Reiser *et al.*, 1955), and by place of testing (e.g. ward and laboratory, Malmö, Shagass and Heslam, 1951). It may also be abnormally high under certain pathological conditions (e.g. kidney disease).

In essential hypertension both systolic and diastolic pressures are raised, and this increase in pressure is attributed to high peripheral resistance resulting from a narrowing of the arteriolar bed. Arteriolar constriction may be induced both by sympathetic impulses and by circulating hormonal agents. Essential hypertension has been studied as a psychosomatic disorder (Katz and Leiter, 1939; Reiser, Ferris and Levine, 1954; and Hamilton, 1955). (Many investigators have stated that hypertensive patients are particularly liable to an increase in blood-pressure in response to emotional stress.)

Experimental studies

Quite large changes in blood-pressure (from 8 to 10 mm Hg) have been observed to follow a variety of simple sensory stimuli, and more complex forms of stimulation such as watching a film or participating in a psychiatric interview. A significantly larger diastolic reaction to an "anger" situation than to a fear situation has been reported by Ax (1953).

Hickam, Cargill and Golden (1948) found an increased mean arterial pressure (from 90 to 99 mm Hg) in normal subjects made anxious by an important examination. Heart rate, stroke volume, cardiac index and peripheral resistance, however, showed more marked changes, and these authors considered that the elevation in blood-pressure represented a relatively slight imbalance between a large increase in cardiac output and a large fall in peripheral resistance. They commented on the great variability of the circulatory response in anxiety.

A survey of the literature by Altschule (1953) led him to the conclusion that there is no evidence that

chronic anxiety or any specific type of emotion, personality or conflict, causes lasting hypertension in normotensive persons. The available studies, which he considered, all referred to normal or slightly raised readings in most instances of neurosis and neurocirculatory asthenia, but patients in this latter category frequently demonstrate excessive rises in arterial pressure (especially systolic) when they exercise.

Arterial pressure in psychosis has also been discussed by Altschule (1953) who, after a comprehensive survey of the literature, considered that the evidence pointed to high blood-pressure in depressed (but not manic) patients. Although a few studies also describe high arterial pressure in schizophrenic patients, most readings reported in this group are in or below the normal range (*see* Altschule, 1953, for references). Shattock (1950) also reviewed a number of studies in which low blood-pressure was found in schizophrenics.

Since the appearance of these reviews there has been little enlightenment from subsequent studies, although some careful investigations of blood-pressure levels of psychiatric patients have been carried out by Malmö and his collaborators. As will be seen from the following descriptions, the variety of stimulus conditions and measures employed precludes a coherent organization of the results.

Measurements from psychiatric patients have often been made while the subjects rested, but as Malmö and others have stressed, response characteristics in addition to resting levels provide valuable data. Another important factor may be the chronicity of the illness. Malmö and Shagass (1952) investigated the blood-pressure responsiveness of several psychiatric groups—chronic and acute schizophrenics and neurotics—and a normal control group, under three conditions: pain stimulation, rapid discrimination and mirror drawing. Auscultatory measurements were made with a standard mercury sphygmomanometer and with a Cambridge recording sphygmotonomograph (the authors referred to the latter as the machine method).

The mean machine scores of acute schizophrenics and neurotics were significantly higher for systolic pressure before and during the pain-stress than those of controls and chronic schizophrenics, but blood-pressure *changes* gave different results. Controls' and chronic schizophrenics' systolic pressure dropped during the pre-test periods, acute psychotics showed a small drop and neurotics failed to show a drop. Mean systolic and diastolic pressures increased with pain stimulation in all groups, but no significant differences were found between groups in respect of the amount of change. It was concluded that since chronic schizophrenics resembled normals in systolic blood-pressure reaction the evidence was inconsistent

with the view that these patients are abnormally sluggish under stress.

During performance of a rapid discrimination and a mirror drawing task a greater rise in blood-pressure was shown by the psychoneurotic group (see Fig. 11.1). The increase between the first and last thirds of the neurotics' blood-pressure curve during mirror drawing

FIG. 11.1. MIRROR DRAWING TEST (CIRCLE)
Mean blood-pressure during second Mirror Drawing Test.
Note continuous rise in curve for psychoneurotics.
(From Malmö and Shagass, 1952.)

was statistically significant. Correlations of blood-pressure measurements during different situations showed that the highest degree of individual constancy in physiological reaction was to be found under conditions of stress.

The hypothesis that neurosis is characterized by defects in physiological regulation of reaction to stress was followed up in another study, by Malmö, Shagass and Heslam (1951). They suggested that defective physiological regulation may show itself in two main aspects of reaction—increased magnitude (or amplitude) and low degree of adaptation, and, therefore, studied the adaptation of the blood-pressure response to repeated brief stresses: the Porteus mazes, normal and inverted, and three cold pressor tests. The earlier finding of lower adaptation in patients was confirmed. Although reactions to the stimuli occurred in both groups, the controls' reactions tended to diminish as the session progressed,

while the patients' reactions tended to persist at the initial level.

It would obviously be of interest to obtain further information concerning the physiological response curves (gradients) of psychiatric subjects during the performance of motor tasks. Some work with normal subjects has been reported by Malmö and Davis (1956); they obtained highly significant gradients of blood-pressure during motor performance, and significant correlations between the steepness of the gradient and performance time, an important finding which requires substantiation.

In view of the interdependence of cardiovascular variables it would be highly desirable to obtain a broader picture of these functions by recording measures such as cardiac output and peripheral blood flow in addition to blood-pressure. Simultaneous measurement of widespread cardiovascular variables presents considerable technical difficulties, however, and Davis *et al.* (1955) found that the periodic application of occluding pressure seriously disturbed all the other variables of the circulatory system.

Summary: Blood-pressure

1. *General conclusions.* An increase in blood-pressure to stimulation is the general rule. Responses have been reported to a variety of sensory and "emotional" stimuli.

Adaptation occurs both to repeated stimulation, and in background level throughout the experimental session: on the other hand, accelerated gradients during performance of a motor task, related to performance time, have been demonstrated.

Relatively high degrees of individual consistency in blood-pressure measurements have been obtained in different situations.

2. *In relation to psychiatric disorder.* The general finding is that resting blood-pressure is normal or slightly elevated in neurotics. Most studies have reported low resting blood-pressure in schizophrenics; on the other hand, higher systolic pressure in acute schizophrenics and consistently higher diastolic pressure in chronic schizophrenics have been found.

With the stimulus conditions employed, changes in response to stimulation do not discriminate between psychiatric groups and normals. There is a little evidence that neurotics show anomalies of adaptation, i.e. they may persist at higher blood-pressure levels during performance.)

PERIPHERAL VASOMOTOR CHANGES

The constriction and dilatation of the blood-vessels is one of the ways in which the redistribution of blood in accordance with the requirements of the organism may be achieved. Those vessels situated near the surface of the skin (and these are most accessible for

measurement of changes in volume) are very directly concerned with the function of regulating body temperature both by exposing a variable blood surface and by altering the rate of flow. Peripheral vasomotor responses are also observed to follow external sensory stimuli, examples of which will be dealt with in this section.

Most measures of peripheral vasomotor activity in humans are indirect because it would be necessary to insert a cannula into the blood-vessels to obtain a direct estimate of the resistance offered by the peripheral blood-vessels to blood flow. The various available methods involve the measurement from the skin surface of such changes as colour, temperature, or volume (of a limb or digit), it being assumed that these are related to changes in the peripheral circulation.

On the assumption that vasoconstriction is accompanied by a diminution and vasodilatation by an increase in volume, the method of volume plethysmography has been developed; in the usual procedure an extremity (e.g. finger) is sealed in a rigid container filled with water or air, the volume displacement of which (following volume changes of the digit) can be recorded and interpreted as giving information on the amount of blood present in the region at the time. By occluding the venous return and measuring volume with respect to time, a measure of blood flow may be derived, viz. dv/dt .

Ackner (1956a) has reviewed some of the techniques for estimating peripheral blood flow, such as thermal methods and the photoelectric plethysmograph used by Hertzman *et al.* (1946). Davis (in Ellson *et al.*, 1952) has described his attempt to use a modification of an electric impedance plethysmograph proposed by Nyboer (1947). The principle in Nyboer's plethysmograph consists of passing a low voltage radio-frequency current through a selected area and recording the changes in impedance of the tissues under different response conditions. In this method measurement is based on the comparison of an original signal with that observed after traversing the area under measurement. One drawback is that so far no satisfactory calibration of impedance plethysmographs with respect to the absolute volume being measured has been achieved (Davis *et al.* 1955).

Both volume and impedance plethysmographs record total volume changes of the area under measurement (e.g. tip of finger) as well as each peripheral pulse beat. The peripheral pulse beat appears superimposed on the total volume change, but these may be easily separated (see Ellson *et al.*, 1952).

Some of the factors which influence peripheral blood flow are temperature, limb position, and interacting effects with other changes in the cardiovascular system. The size of the response following a stimulus is partly related to the pre-stimulus degree

of dilatation; little in the way of reflex constriction can be expected if the vessels are not dilated beforehand (Ackner, 1956b). Vasoconstriction is controlled mainly by sympathetic nerves and also in part by hormones circulating in the blood; the distribution of vasodilator fibres throughout the parasympathetic nervous system is not generally conceded.

Vasomotor responses may be quite specific to particular regions and there is no evidence of a general vasoconstrictor effect under all stimulus conditions; indeed, constriction of one area (finger) and dilatation of another (chin) to identical stimuli have been found (Davis *et al.*, 1955). Many authors have noted a relationship between mental tasks, alerting stimuli, and changes in volume of limb extremities.

Adaptation

It has frequently been observed that this response adapts to repeated stimuli, but there are few precise experimental data apart from the recent careful attempt to measure adaptation to a repeated tone which has been reported by Davis, Buchwald and Frankmann (1955). These authors (using an impedance plethysmograph) measured amplitude of response as the amount of decrease from the level prior to onset of each stimulus (a 98-db 800-cycle tone) to the maximum constriction following the stimulus, and converted these values to percentages of maximum response. The results of several statistical tests did not indicate the presence of a stimulus repetition effect, either in amplitude or latency of response, although a small decrease in the size of the response was noted. A significant decrease in magnitude of the volume pulse was, however, observed.

Latency and extinction of vasomotor functions were also studied in a further experiment, in which three levels of stimulus intensity were used: a 1,000 cycle tone of 70, 90 and 120 db (Davis *et al.*, 1955). Volume pulse and finger volume showed a small increase in response size from 70 to 90 db and a much larger one (statistically significant) from 90 to 120 db, the log response being a linear function of the decibel values (a result similar to that obtained by Hovland and Riesen, 1940). Although decreasing response size upon repetition was noted, no adequate level of statistical significance was reached.

Somewhat different results for chin volume were obtained. Dilatation, rather than constriction, appeared to be the typical response and the latency was shorter than that of the finger volume response. When first and last quarters of the recording session were compared, there was a decrease in response, significant at the 5 per cent level, but there was no significant relation between response size and stimulus intensity. (These results are summarized in Table XI.2.)

Cutaneous Stimuli

The intensity of certain forms of stimulation (electric shock, heat and sharp needles) and vasoconstriction and vasodilatation was investigated by Nafe and Wagoner (1936, 1938). These authors claimed a relationship between intensity of stimulation and amount of vasoconstriction, but gave no measurements.

A series of tactual stimuli—heat, heat “control,” cold, pressure, prick and tickle—was applied to the skin of the left forearm in a study by Davis *et al.* (1955). The volume pulse response to the heat-control, cold, pressure and prick stimuli was a decrease in amplitude which reached its minimum about eight to twelve seconds after stimulus onset, and, except in the case of the prick stimulus, had returned to normal by the end of the period of measurement, which was about seventeen seconds. The most marked constriction effect was produced by the prick stimulus.

Right index finger and chin volume responses were both dilatation. During the seven seconds or so following stimuli only the pressure stimulus produced a significant finger dilatation; with the chin, the dilatation was significant for pressure and heat stimuli. After seven seconds following stimulation, finger dilatation was still significant for the pressure stimulus and chin dilatation significant for the heat stimulus.

The results indicated that some tactual stimuli produce a vascular *dilatation*, an effect which is opposite to the finger *constriction* effect observed to follow auditory stimulation.

Experimental Studies with Psychiatric Patients

There is an interesting literature, consisting mainly of observations but also a few experimental studies, on the presence of peripheral vasoconstriction in schizophrenic subjects. This may be associated with cyanosis, or cold, blue extremities, (which seems to be due to a constriction of the small arterioles of the skin) a condition which has long been described in psychotic patients and which may disappear on remission (Shattock, 1950 and Ackner, 1956a review this work).

There are also many scattered studies concerning excessive peripheral vasomotor responses of schizophrenics to external cooling (see Shattock, 1950, and Ackner, 1956a) and these have led to the opinion that schizophrenics show some impairment of the normal mechanism of vascular control (Richter, 1957) and that this circulatory defect may be located in the autonomic controlling centres situated in the hypothalamus (Gellhorn, 1953; Richter, 1957). It has been pointed out that the prolonged vasoconstriction appears to be necessary to preserve body-heat and is not a consequence of emotional disturbance since it

is commonly observed in subjects who are withdrawn and manifest little emotional disturbance (Ackner, 1956a).

These general observations and impressions require precise experimental confirmation, and on the basis of existing evidence one would suppose that the careful study of cardiovascular responses of schizophrenics in relation to changes in external temperature would provide rewarding results.

There are few systematic studies which have aimed directly at relating vasomotor reactions to assessments of emotions such as “anxiety,” but there are two interesting contributions to the topic. The first is a series of investigations carried out by Van der Merwe and Theron (1947), Theron (1948) and Van der Merwe (1948) using a Goetz finger plethysmograph. Measures obtained included rate of finger volume change with tasks (arithmetic problems), total reflex volume change with tasks, and variations in pulse volume.

Correlations of 0.409 (Van der Merwe and Theron, 1947) and 0.294 (Theron, 1948) were found between rate of finger-volume change with tasks and emotional stability as measured by the Bell scale, that is, those subjects who had high emotional adjustment scores tended to have a higher rate of change in finger volume (indicating greater degree of vasodilatation). These correlations were increased when adjustment was made for differences in initial pulse volume.

Similar measures were used in a subsequent experiment by Van der Merwe (1948) using the fifty subjects in Theron's (1948) experiment as a control group, and, in addition, twenty-one neurotic patients, eight with symptoms of anxiety and fifteen with hysterical and neurasthenic symptoms. Three measures—pulse volume before deep breathing, pulse volume before tasks, and rate of finger-volume change with a cold water test—were significantly *smaller* in the anxious patients than in the control subjects. *Larger* responses in the hysteric than in the normal group were obtained with all measures of pulse-volume and digital-volume change. Since both patient groups differed in opposite directions from the controls, a marked difference was found between the two patient groups: almost all the effects were significant at the 1 per cent level, indicating greater constriction or increased vasomotor tone in anxious patients than in hysterics.

The other study concerned with neurotic patients and their vasomotor responses has been reported by Ackner (1956b). His experiment utilized measurement of vasomotor activity while the subjects went to sleep because the tendency to vasodilatation rather than vasoconstriction should be observed when emotional factors are reduced or absent. It would follow that relaxed subjects, lacking apparent vasoconstriction, would manifest little change during sleep, but

emotional subjects showing marked constriction would be expected to show greater changes. Secondnal was used as a sleep-producing agent, because preliminary experiments with a short-acting barbiturate had shown that subjects did not vasodilate whilst awake.

In Ackner's plethysmographic study, volume changes of the finger tip were transmitted as changes in pressure applied to a beryllium copper bellows, constructed in the form of a variable condenser. The subjects lay on a bed with the left arm supported so that the arm remained at heart level. Three groups of subjects were used: (i) an anxiety group (N = 13, 10 female and 3 male); (ii) a non-anxiety clinical group (N = 10, 8 female and 2 male); (iii) a control group (N = 10, 3 female and 7 male). Average ages of the groups were similar.

Measurements of initial pulse-volume amplitude, and maximum pulse-volume amplitude during recording were obtained. The differences between the three groups in the pulse volume were not statistically significant, but changes occurring during sleep were highly significant (see Table XI.4). These measures of

TABLE XI.4
PULSE-VOLUME CHANGES IN CONTROLS, NON-ANXIETY PATIENTS AND ANXIETY PATIENTS DURING REST AND SLEEP

(From Ackner, 1956b)

	Mean initial pulse volume (cu mm)	Mean pulse-volume-increase (cu mm)
<i>Resting tests</i>		
Controls	9.4	1.0
Non-anxiety patients	5.8	1.6
Anxiety patients	3.4	1.0
<i>Sleep tests</i>		
Controls	10.1	0.55
Non-anxiety patients	6.3	2.3
Anxiety patients	4.9	12.3

Range of pulse-volume increase during sleep (cu mm)

Controls	0-2.5
Non-anxiety patients	0-5.0
Anxiety patients	6-23.0

change did not overlap at all between groups, the anxiety patients being completely differentiated from the other two groups by the magnitude of their vasodilatation. Similar results were obtained for pulse-rate changes during sleep, although the differences were not so significant. Two of the anxious patients who recovered from their disturbed emotional

state were found, on retest, to show little or no change in pulse volume during sleep.

Ackner concluded that: "vasoconstriction of the skin vessels on an emotional basis is part of a bodily alerting reaction to stress, which probably serves the function of diverting blood to areas which are becoming mobilized for offensive or defensive action." He considered that increased sympathetic activity along the vasomotor pathways seemed to be the most likely explanation of the maintained vasoconstriction.

Summary: Peripheral Blood Flow

1. *General conclusions.* The degree of constriction following a stimulus depends upon pre-stimulus level of dilatation. It has been found that constriction of the pulse and finger volume and dilatation of facial areas follow auditory stimuli, and dilatation of finger and chin volume follows certain cutaneous stimuli.

No adaptation of finger volume response and latency to a repeated tone was found by Davis *et al.* (1955) although adaptation was present in volume pulse measurements.

The finger volume decrease following a stimulus occurs somewhere between 5 and 7.5 seconds, reaching a maximum about 12 to 15 seconds after the stimulus with the method used by Davis *et al.* (1955).

Vasoconstriction is controlled by sympathetic nerves. Sleep is generally accompanied by increasing vasodilatation.

2. *In relation to psychiatric disorder.* There are many observations that schizophrenics are characterized by excessive peripheral vasoconstriction, but only a little precise experimental evidence to the effect that schizophrenics show excessive drops in skin temperature to cooling. These reactions are believed to be a consequence of the normal physiological preservation of body heat.

There is evidence of greater vasoconstriction in anxious patients, more clearly demonstrated during sleep. The rate of change in finger volume with commencement of certain tasks was found to correlate with a measure of emotional stability. One small group of hysterics was found to show greater vasodilatation than normals.

Skin Temperature

Skin temperature has been commonly used as an index of peripheral blood flow because in general the temperature of the skin depends upon the amount of heat brought to it by the blood-stream and upon the amount of heat lost from its surface (Plutchik, 1956; see also Ellson *et al.*, 1952, and Ackner, 1956a) but there are few detailed investigations of the actual relationship between changes in blood flow, vascular volume and skin temperature. There may be a complex interrelation under some conditions but independent

variation under others (Fetcher, Hall and Staub, 1949).

Many studies have pointed to a diurnal temperature rhythm. Kleitman (1939) reviewed many of these investigations, most of which reveal a maximum value in the afternoon or evening hours, and a minimum in the early morning hours: he thought that this rhythm could be accounted for by the influences of food intake, muscular activity and sleep. Changes in vasomotor tone (such as could be induced by altering limb position) have also been found to affect skin temperature, finger volume and pulse volume (Goetz, 1950). It is obvious that many other variables will influence skin temperature; factors such as room temperature and humidity, time since ingestion of food, muscular activity and posture of the subjects as well as time of day must be reckoned with (*see* Sheard, 1947; Wenger, 1948; Flecker, 1951, and Ackner, 1956a).¹

There are three main measuring techniques (Plutchik, 1956): (i) ordinary mercury thermometers, (ii) thermocouples or thermopiles attached to the surface of the skin, and (iii) radiometers. The latter measure heat radiation which, Plutchik suggests, depends not only on evaporation and blood flow in the skin directly under the instrument, but also on blood flow in deeper tissues. Both he and Ackner (1956a) have indicated advantages and disadvantages of the available instrumentation.

Although the literature on the psychophysiological functions of skin temperature in particular is scant and in general uncoordinated, a few observations emerge which, if corroborated, would deepen our understanding of this measure.

The relation of skin temperature changes to initial level has been considered by Plutchik and Greenblatt (1956) on very limited data obtained during psychiatric interviews. Finger temperatures were found to vary between the range 20° to 36°C.

The authors' tentative conclusions were that magnitude, rate and duration of subjects' temperature changes were related to initial (i.e. pre-change) temperature. They observed that larger rises occurred when the initial temperatures were low, that there was a tendency for temperature to rise at a faster rate from low than from high levels, that the lower the initial temperature the longer the rise would continue and that the fastest rate of change of skin temperature from any starting point was always an increase rather than a drop.

A certain time is required for warmth adaptation to room temperature; Flecker (1951), using a light

weight thermocouple attachment fitted to the subject's finger-tip, observed that the majority of his subjects' skin temperatures reached a maximum within the first twenty minutes. He also observed that the total range of measurements was approximately 22° to 35°C.

An early study by Helson and Quantius (1934) using a thermocouple held by the subject against the infra-orbital region near the nose, showed skin temperature changes as large as 4°F to a number of stimuli, including ice to neck, cold water, noise of a pounding hammer, a needle prick, etc., and also to verbal warning of these stimuli. Increases of temperature to the stimuli occurred more frequently than decreases (one hundred and thirty-three increases, sixty-six decreases) and there were sixty-three instances of no change. The authors claimed that slight change in the position of the thermocouple and bodily movements did not affect the readings. Variability in the direction of the response was also observed by Flecker (1951); most subjects in his study showed drops in skin temperature during a word-association test, and an increase during reading. In a learning situation twenty-three subjects showed a drop, four no change, and eleven an increase of finger temperature. These few studies are of some interest, but there are apparently no reports of research on skin temperature as the dependent variable measured in relation to stimuli varied in intensity, duration or number of repetitions.

Increase in skin temperature both to a spark stimulus and during induced tension (with a greater reaction to the spark) was recorded by Baker and Taylor (1954) by means of a thermistor placed against the palm of the left hand; the correlation table given by these authors shows that correlations between skin temperature and skin resistance vary under different conditions.

Many workers have reported excessive drops in skin temperature in schizophrenic subjects as a result of external cooling (*see* H. Freeman, 1939; Finkelman and Stephens, 1936) and such results have contributed to the view discussed in the previous section that temperature-regulatory centres may be less responsive in schizophrenia than in normal subjects.

In his studies on autonomic balance Wenger (1948) obtained two measures of resting finger temperature by means of a laboratory thermometer held by the subject between the fingers. The first reading (taken at the beginning of the session) gave an average of 34.9°C (S.D. 1.0) for four hundred and eighty-eight students and 34.1°C (S.D. 3.6) for two hundred and twenty-five operational fatigue patients ($p < 0.01$). The two variables which best reflected the improvement in patients after a period of convalescence were finger temperature (first reading) and palmar conductance. Finger temperature did not, however, discriminate between a group of anxiety states ($N = 49$) and a group of mixed neurotics ($N = 49$) but when

¹ It has been emphasized that there is no such thing as a "normal" skin temperature (as there is of mouth temperature) and that one must therefore define the conditions under which any measurement is obtained (Sheard, 1947).

all patients were combined and compared with a normal group, first finger temperature reading again discriminated significantly, patients having the lower finger temperature.

It is possible that this result may be related to the greater vasoconstriction (measured by means of a plethysmograph) which has been found in anxious patients, and simultaneous recordings of the two variables under different stimulus conditions should provide interesting data concerning the degree of similarity of their reactivity.

Summary: Skin Temperature

1. *General conclusions.* There is a little evidence that the magnitude, rate and duration of a subject's temperature changes are related to pre-change temperature. Rises in temperature were observed to have different characteristics from drops.

Skin temperature may increase or decrease following sensory stimulation, probably in part dependent upon the nature of the stimulus.

The modal rate of rise appears to be 0.6° – 0.7° C per minute, and the response is fairly slow with a duration of generally less than one minute (Plutchik and Greenblatt, 1956).

2. *In relation to psychiatric disorder.* A few findings point to greater reactivity of schizophrenics to cool temperatures (see summary under peripheral blood flow). One study reports lower skin temperature of neurotics.

Heart Rate

The heart may increase its output in two ways, by increasing its output per beat, and by increasing beat frequency. The magnitude of the muscle potential occurring with each heart beat enables recordings to be made without difficulty; both the E.C.G. and the cardiometer (which counts beats) are in general use, but E.C.G. "artefacts" are commonly used from other recordings (e.g. skeletal muscle).

Diurnal curves of heart rate, closely following those of body temperature, have been described, and the individual's sex, degree of muscular activity and digestive state are factors which may influence heart rate.

Studies concerning cardiac changes in relation to emotional states are legion, but few provide precise data; in common with reports on other physiological variables, many deal with reactions during psychiatric interview, or other poorly-defined stimuli. Although the evidence appears to be overwhelming that many stimuli increase heart rate, the mechanism producing this reaction is likely to be complex. In addition to the direct effects on the circulation of "emotional" stimuli there may be indirect effects; for example a lowering of the peripheral resistance may cause a rise in cardiac output.

Some early investigations of cardiac effects following surprise stimulation led to the claim that changes in the wave-form of the electro-cardiogram were related to the point in the cardiac cycle at which the stimulus occurred, but it has since been demonstrated that these E.C.G. changes may be artefacts arising from extra-cardiac activity such as muscular activity of the arms and shoulders (Springer, 1935).

Using several surprise stimuli (a tipping chair and klaxon horn) Springer found a rapid increase in heart rate following stimulation which reached a maximum by the third or fourth beat and decreased almost to basal level by the end of ten seconds. Increments up to twenty-five beats per minute following a gun shot were reported by Berg and Beebe-Center (1941) and habituation effects noted. These authors give the repeat reliability of their index of cardiac startle as 0.53 ($N = 33$). They observed that a different stimulus or a lapse of time is sufficient for the disinhibition of the startle response.

Altschule (1953) reviewed the literature on the cardiovascular effects of emotional disorders and came to the conclusion that the cardiac rate is normal or only slightly accelerated in patients with neurosis or neurocirculatory asthenia, but that this latter group show excessive physiological and metabolic changes (such as severe increase in heart rate) when they exercise. When unselected psychiatric patients were separated on the basis of presence or absence of heart complaints (pre-cordial pain, palpitation, etc.) those with the symptoms were found to have a significantly higher heart rate than those without (Malmo and Shagass, 1949b). The results of two similar studies concerning heart rate of neurotic and normal subjects during pain stimulation are conflicting (Malmo and Shagass, 1949a, Malmo and Smith, 1955).

The findings in relation to schizophrenia are confusing. Malmo, Shagass and Smith (1951) found that mean heart rate of chronic schizophrenics was reliably higher than controls during pain stimulation, and increased markedly upon beginning a rapid discrimination task, in contrast to the relatively flat curve for normal controls. Jurko, Jost and Hill (1952) also found heart rates of schizophrenics higher than those of controls and neurotics, but they observed a lower change of rate on stimulation. Kivisto (1953) reported no differences in rate between psychotics and normals. There is almost certainly a marked variability of heart rate in an individual patient, irrespective of the type of psychosis present.

The Cardiovascular System: Organization of the Responses

No adequate integration can be made of the results of changes in cardiovascular variables without reference to their dynamic interaction within the

circulatory system, within which regulatory mechanisms of great precision and sensitivity operate to maintain a homeostatic adjustment. To understand the widespread cardiovascular changes which occur following a stimulus it is necessary to have some knowledge of the underlying physiological mechanisms, a knowledge which could lead both to a more rational choice of the variables to record and a better

continued vasoconstriction (with some recovery), stronger pressure pulse, subnormal heart rate, and probably increased systolic as well as diastolic pressure. The peripheral constriction of the first phase seems to bring on the second phase by acting in two directions: by increasing mean arterial pressure it activates the heart-slowing reflexes, and by increasing venous pressure and flow it returns more blood to the heart and increases the force of its beat and the amount of blood ejected.

FIG. 11.2. PUPILLOGRAM (A) AND DIFFERENTIAL ANALYSIS (A') OF THE NORMAL REFLEX TO LIGHT IN MAN

(A) The pupillary diameter (in millimetres) is plotted against time (in 0.1 sec). After a latency period of about 0.2 sec, the pupil contracts in response to light, and redilates some time after the stimulus has come to an end. Contraction and redilatation consist of a faster primary and slower secondary phase.

(A') Contraction and redilatation within each successive tenth of a second are plotted (in 0.1 mm) against time (in 0.1 sec). Pupillary contraction and redilatation consist of different waves of increasing and decreasing speed of motion

C-wave (contraction wave), the ascending branch corresponds to the "primary contraction phase," the descending branch to the slower "secondary contraction phase" of the pupillogram. D-wave (primary dilatation wave) and E-wave (secondary redilatation wave), in man the two redilatation waves tend to merge.

(From Lowenstein and Loewenfeld, 1952a)

interpretation of the observed responses (Davis *et al.*, 1955).

Some of the results obtained by Davis *et al.* (1955) in measuring specific cardiovascular responses to various stimuli have been described in the preceding sections. They have integrated their findings to describe an overall type of cardiovascular response, arising from auditory stimulation, the initial elements of which appear to arise predominantly from sympathetic activity. In summary, this is characterized—

by a first phase of cardiac acceleration, vasoconstriction, smaller pressure pulse, and probably increased diastolic pressure. The second phase is characterized by

Pupillary Reactions

The size of the pupil is varied by two smooth muscles working antagonistically: the dilator, which is activated by sympathetic nerves and produces the pupillary condition known as mydriasis, and the constrictor, which is activated by parasympathetic nerves to produce the state of miosis. The simple concept of reciprocal action of the two autonomic branches is widely held, but Gellhorn (1953) considers it too limited to give an adequate description of the mutual relations of sympathetic-parasympathetic innervation of the pupil.

A number of stimuli produce changes in pupillary diameter; for example, pain and nociceptive impulses arising from various parts of the body are followed by dilatation, and exposure of the retina to light produces pupillary constriction. Under normal conditions pupil size may vary with age, refractive errors, the state of light and dark adaptation, and numerous other factors. In the normal individual there are constantly small irregular fluctuations giving rise to a state of pupillary unrest which may be due to a combination of biological and physical causes.

With the development of the technique of infra-red pupillography (details of which are given by Lowenstein and Loewenfeld, 1950) it has become possible to measure pupillary reactions under conditions of both dark and light adaptation. By this means the shape of the pupillary response of man and other animals to a variety of stimuli, and under many conditions (e.g. experimental lesions at different levels of the C.N.S.) has been studied (Lowenstein, 1946, Lowenstein and Loewenfeld, 1950a, 1950b, 1951, 1952a, 1952b). These authors found that the reaction to light could be analysed into three stages, a primary contraction phase predominantly due to parasympathetic factors, and secondary and tertiary phases predominantly due to sympathetic factors. In normal human subjects the pupillary reflex to light consists of a contraction which is preceded by a latency period of between 0.2 and 0.3 sec, and is about 3 mm in extent. (See Fig. 11.2.)

Adaptation

It has been reported that when the light reflex of the pupil is elicited again and again (fifty to one hundred

times or more) the latency period becomes longer, a refractory period develops, and the constriction becomes increasingly sluggish both in extent and duration. At some point (earlier with weak stimuli) the pupil no longer reacts to the light, but if a psychological or sensory stimulus is interposed between light stimuli, the pupil reacts again to the subsequent light stimulus, a phenomenon which Lowenstein and Loewenfeld (1952*b*) term "psychosensory restitution."

Restored reflexes can again be fatigued, but with each alternation of fatigue and restitution the number of stimuli necessary to reach exhaustion becomes smaller. It has also been claimed that the general fatigue produced by the stress of a working day adds to the fatiguability of the pupillary reflex to light (Lowenstein and Loewenfeld, 1952*a*).

The shape of each pupillary reflex to light is considered to indicate the degree to which the centres of control are disintegrated by fatigue. The various autonomic centres concerned with the integration of pupillary reflex activity show different degrees of fatiguability: sympathetic centres fatigue before parasympathetic centres, and cortical before sub-cortical (Lowenstein and Loewenfeld, 1952*a*, 1952*b*).

These authors have also studied the effects of experimental lesions placed along the pupillary pathways of rabbits, cats, and monkeys, with the purpose of providing a basis for pupillography as a diagnostic indicator of clinical lesions of the A.N.S. (Lowenstein and Loewenfeld, 1950*a*). The variety of pupillographic curves obtained has been fully described, and one of the conclusions reached is that all the pupillographic syndromes produced by such lesions in animals are observed in man as clinical manifestations of pathologic processes of corresponding sites.

Experimental Studies with Psychiatric Patients

Granger (1953) reviewing work on the pupillary responses of different psychiatric groups points out that it would hardly be surprising if such responses were found to be of value in the study of personality and functional disorders, in view of the multiple neural connexions of the pupillary pathways with different levels of C.N.S. functioning.

May (1948) observed a high incidence of diminished pupillary response to pain, light and muscular effort in schizophrenics, a finding which he connected with the general hypoactivity which schizophrenics show. This suggestive study should be followed up with a more objective method of measuring pupil size.

The analysis of pupillary reactions to light carried out by Lowenstein and Westphal (1933) led them to classify responses into four types: (1) a group which is rapid in both contraction and dilatation; (2) a group prompt in contraction and slow in dilatation (this type occurred most commonly); (3) a group

slow in contraction and prompt in dilatation, and (4) a group sluggish in both contraction and dilatation. These four types of responses are believed to represent four kinds of equilibrium of sympathetic-parasympathetic activity, and to be constitutionally determined. The authors claim a significant relationship between the first type of reaction and manic-depressive psychosis and between type (4) and certain schizophrenics (see Fig. 11.3.) In catatonic schizophrenics yet another type of reaction was observed,

FIG. 11.3. THE DISTRIBUTION OF THE FOUR LIGHT-REACTION TYPES OF NORMALS, SCHIZOPHRENICS, AND MANIC-DEPRESSIVES

characterized by a long latency period, a rapid reaction to light and a long latency period for the redilatation followed by a full dilatation (see also Levine and Schilder, 1942). Such findings are of great interest, and merit further quantitative investigation in relation to selected groups of patients.

Pupil size of neurotics was investigated by Wenger (1948) in his study of autonomic balance; the measure obtained (of "static" pupillary diameter) failed, however, to correlate with other autonomic measures and to differentiate between groups. As Granger (1953) has pointed out in his review, the technique Wenger used was relatively crude, and the static type of record obtained was possibly not the most appropriate for investigating this type of problem.

Respiration

Woodworth and Schlosberg (1954) comment that respiration involves a reflex-automatic mechanism which primarily serves a metabolic function but which is also very responsive to changes in the organism's behaviour. Davis (in Ellson *et al.*, 1952) has discussed some of the mechanisms underlying respiratory movements, and has considered some of the "inputs to the breathing system" which initiate the changes.

Devices for recording breathing have been described by Woodworth and Schlosberg (1954) and by Davis (in Ellson *et al.*, 1952). There are two traditional methods, one depending on the volume of the inspired and expired air (using B.M.R. equipment) and the other (the pneumograph) depending on changes in girth of the chest and abdomen. A newer type of respiratory recorder has been described by Ackner (1956c); this is a rubber tube, filled with mercury, which constitutes a directly-varying resistance in an electrical measuring circuit. Yet another method depends on temperature variations picked up from inhaled and exhaled air and recorded by means of a thermocouple. In one study which employed both thermal and pneumograph techniques, similar results were obtained (Davis, in Ellson *et al.*, 1952).

Measures to an accepted index are difficult to obtain with the pneumograph, and results have inevitably to be given in terms of ratios. The extreme irregularity of the breathing amplitude has been stressed (Altschule, 1953) and data given on the high variability of breathing responses (Davis *et al.*, 1955). Wenger (1948) obtained test-retest correlations of about 0.5 to 0.6 for four respiratory measures obtained on two successive mornings ($N = 54$); three of these correlations dropped when the interval was three or four months but one, a measure of respiratory period, remained almost unaltered at $r = 0.65$.

EXPERIMENTAL STUDIES

The effect of various stimuli on respiratory changes is not clear. Altschule (1953) refers to some very early psychological experiments in which startle was reported to cause an immediate cessation of respiration followed by an increase of rate above normal. Stresses of various types may apparently give rise, in rather unpredictable fashion, to either increases or decreases in respiratory rate, although from the available literature Altschule considers increases to be more common.

Davis *et al.* (1955) have investigated breathing responses to a variety of simple stimuli. They found that breathing amplitude increased to a tone of 98 db and reached a maximum as late as 15 to 20 sec after the stimulus. They failed to observe adaptation effects to ten repeated stimuli; on the contrary, the means for the last half of the series tended to be higher than those for the first half, suggesting a facilitation rather than habituation of response to repeated stimuli. A tendency (not statistically significant) was also found for breathing cycle time to increase in response upon repeated stimulation.

Respiratory response also increased to auditory stimuli of increasing intensity (70, 90 and 120 db). The response to the stimulus of 120 db was significantly greater than that to the weaker tones; the

difference between responses to the two weaker stimuli did not approach significance (*see* Table XI.2).

Repetition effects differed with the stimulus intensities employed; a *decrease* in response to the strong stimulus was found ($p < 0.01$) and an *increase* (just significant) to the weaker stimuli. The measurement of duration of breathing cycle during the 15–20-sec interval following stimulus showed an effect of stimulus intensity, significant in the case of the strongest stimulus.

The authors have suggested that the evidence indicates a certain amount of independence of the two respiratory measures (duration and amplitude changes) but it is worth noting that these particular variables were selected for statistical treatment from a number of rather complex response curves. An attempt was made to explain the changes in breathing observed in terms of physiological mechanisms such as decrease in vagal feed-back and increased arousal of the inspiratory centre.

Most of the work which has been carried out with respiratory measures of psychiatric patients has used vague stimulus conditions, such as "ideational" stimuli, psychiatric interviews, etc., and has paid little attention to the reliability, quantification or statistical treatment of the data obtained. It has been observed in several studies that the respiratory responses of neurotic and psychotic subjects differ from those of normals. Altschule (1953), however, considered that respiration is normal, or only slightly raised, in neurotic conditions, and shows no consistent pattern of change in patients with manic-depressive or schizophrenic psychoses. But most of the studies which he has reviewed in his book suffer from the lack of quantification observed above.

The significant findings of greater respiratory irregularity in anxious patients in response to painful stimuli reported by Malmo and Shagass (1949a) were not confirmed in a subsequent study (Malmo and Smith, 1955).

Muscle-action Potentials

A classification of the different techniques used to measure muscle tension has been made by R. C. Davis (1942). He favoured surface electromyography—the direct recording of action potentials from muscles—and with the advent of high-gain amplifiers this method has been quite widely used in psychological experiments. The present section will be confined to electromyographic (EMG) studies since these are most directly related to muscular activity; it should be pointed out that the relationship of measurements made by this method to other means of assessing muscle tension is largely unknown.

The difficulties attendant upon EMG recording and

the instrumentation required have been well discussed (J. F. Davis, 1952) in a monograph which also describes and considers the various bipolar surface electrodes in common use, and which gives details of the standard electrode placements used in the Montreal laboratories.

The signal obtained from surface electromyograms is compounded of many asynchronously firing motor units; from these arises the typical record of muscle spikes differing in amplitude and frequency. It is, of course, the electrical potential difference between the two electrodes which is fed to the amplifier as the input signal.

The quantification of the EMG record presents a formidable task, and, to overcome the difficulty, integrating devices are frequently used in conjunction with electromyographs. Most of the integrators described deal only with the magnitude of the signal (i.e. total charge), and do not discriminate between frequency and amplitude (R. C. Davis, 1948a; J. F. Davis, 1952; Sainsbury and Gibson, 1954). A basic assumption is that the amplitude of the EMG is highly correlated with increase of muscle activity. Travis and Lindsley (1931) have shown that with increasing intensity of contraction the frequency and voltage of the recorded waves increase, and Malmo, Shagass and Davis (1951) also found that their integrated measures of muscle potentials increased with the amount of pull exerted on a dynamometer. But, in another study relating the human EMG to muscle tension, differences were reported in the integrated output depending on whether isometric or isotonic tension was developed (Inman, Ralston *et al.*, 1952). In this study the electrical output as revealed by the integrated EMG closely paralleled the tension in a muscle contracting isometrically, but not when the muscle was allowed to vary in length.

The modal frequency of muscle firing has been estimated at about 45 c/s (J. F. Davis, 1952) and sine waves of this frequency have been used as calibrating signals although higher frequencies are generally observed with needle electrodes and during muscle activity (with any form of electrode). Nevertheless, it is open to question whether the characteristics of the sine-wave signal are comparable with the spiky muscle signal which is to be integrated.

Units of measurement are generally reported in terms of microvolts, on the assumed basis of a constant relationship between peak and mean amplitude, but the term may be a little misleading (J. F. Davis, 1952, has discussed this problem). Only where standard equipment and procedures exist, for example, within a particular laboratory, is it possible to make direct comparisons of individuals' results.

Increased activity of the skeletal musculature has been reported in respect of a wide range of stimuli;

obviously overt movements are accompanied by increases in motor unit discharge, but measurements obtained during situations where the subject is engaged in mental activities such as imaging (Jacobson, 1932; Shaw, 1938), listening (Wallerstein, 1954) and memorizing (Davis, 1939) also reveal changing levels of activity.

Muscle-action Potentials and Performance

There is an interesting literature on the relationship of muscle tension to performance, but much of this research, carried out many years ago, used a variety of tension measures other than electromyography. Any adequate summary of this sort of investigation would need to consider the many tension measures and their interrelationships, and so is beyond the scope of the present section. There remain, however, a number of EMG studies relating muscle-action potentials to various movements, tasks, etc. These have concentrated on different aspects of the total problem; some have considered the pattern of tensions—both focal and remote—in subjects engaged in a task, while others have considered the effects of these tensions upon quality of performance.

Meyer (1953) considered from the available evidence that muscle tension is typically generalized under most of the conditions commonly associated with difficult performance, e.g. lack of practice, prolonged work periods, distractions, complex materials and increased incentives. He has reviewed some of the studies dealing with changes in the distribution of muscle tensions during learning with, and without, artificially induced tensions. He pointed out that the sequence of elimination of tension during practice at a task is such that tension changes are from generalization to focalization. When induced tensions are used, facilitation appears most pronounced early in learning, while late-in-learning tension interferes with performance. In the natural learning situation (i.e. with no artificially induced tension) one of the conditions which produces generalized tension appears to be lack of practice, and Meyer has suggested that a positive role may be assigned to the tenseness of the individual who has just begun to learn, and that the optimal conditions for the novice are not the same as those for the skilled performer.

A review of the evidence led him to the conclusion that interacting responses are necessarily overlapping responses. To account for the way in which overlap is translated into interaction he suggested that simultaneous neural patterns may converge and summate to produce altered amplitude or latency of a response. Changes in the effects of induced muscular tension from facilitation to interference were assumed by Meyer to be related to greater excitation of inappropriate rather than appropriate motor neurons.

Interference with a movement of extension, for example, would be produced by "inappropriate" excitation of sufficient flexor cells to the point of threshold. On the basis of such arguments he developed a theory of efferent neural interaction to account for the effects of induced muscle tension upon both learned and unlearned responses.

Dealing with performance at a fairly simple level, R. C. Davis (1956b) has also hypothesized that the similarity of response patterns is the important factor in determining whether they will facilitate or inhibit each other, and he maintains that the rules of combination (or interaction) of simultaneous responses can best be ascertained by first finding the electromyographic pattern produced by single responses. These single patterns when combined with others might, of course, reinforce one another, neutralize one another, or have a mixed effect, according to the extent of their similarity.

Two completely independent patterns, having no overlap at all, would not be expected to interact but two responses requiring simultaneous actions of the same sort in the same place would be expected to produce the required vector sum more readily, and eventually facilitate the overt response by affecting its magnitude or latency.

Another aspect of the whole problem of the interaction of simultaneous "responses" is the relationship of existing muscle tensions (which are not themselves necessarily connected with overt movements) to performance. For example, Kennedy and Travis (1948) demonstrated that decreasing muscle-action potential output of the supraorbital muscles was accompanied by decreasing "alertness" and poorer reaction-times. R. C. Davis (1940) also found an inverse correlation between simple reaction-time and immediately preceding activity of the responding muscles; yet, as he points out, a high degree of muscle tension has hitherto been considered undesirable—a variable to be minimized for efficient performance.

It would seem likely that the conceptions used are probably too gross to lead to clear results, e.g. "good" performance is not likely to be a unitary affair, and tension produced by distraction or dynamometer gripping may well have different effects (R. C. Davis, 1956b). Several studies based on the simple hypothesis that the nature of the foregoing muscular activity will shape the developing response have been reported by R. C. Davis and his colleagues (summarized by R. C. Davis, 1956b). He has offered the suggestion that if *prior* excitation is in all respects like the desired response, its presence will be facilitative; if prior excitation is incompatible with the response to be made, inhibition and so poorer performance will occur.

Gradients of Muscle-action Potentials during Performance

A series of investigations on gradients of muscle-action potentials during a variety of activities has recently been reported. Gradients have been observed in the forearm during mirror drawing (Smith, 1953), in the chin and extensor muscles of both arms during listening (Smith, Malmo and Shagass, 1954), and in the forehead and chin while attending to several repetitions of a short story and an essay (Wallerstein, 1954). On this latter occasion gradients did not occur in the forearm extensors.

Bartoshuk (1955a) also investigated forearm and chin gradients of tension during mirror drawing, and showed that forearm EMG gradients were not paralleled by gradients in drawing speed, and so could not be attributed to them. He proposed the hypothesis that EMG gradients reflect the subject's motivation, and followed up this suggestion in a further study (Bartoshuk, 1955b). He argued from two assumptions—that both steepness of EMG gradients, and performance, are direct functions of the strength of motivation to perform a task—to the hypothesis that steepness of EMG gradients should be positively correlated with performance.

His results showed that the marked individual differences in gradient slope, when subjects were equated for amount of practice, were directly related to differences in quality of performance, measured by time and accuracy. In another study investigating the effects of incentive, difficulty and "goal structuring" on tracking performance it was found that the incentive was the primary factor in raising the EMG gradient but the relation of gradient slope to performance was not strongly substantiated (Surwillo, 1956).

Malmo and Davis (1956) have considered these EMG gradients as indicators of a dimension of arousal, along which states such as motivation might be placed; they use the term arousal to designate an intensity dimension of behaviour, following up the suggestion made by Duffy (1951) that two basic dimensions of arousal—intensity and direction—might replace the traditional classifications of psychology. These authors, using a procedure similar to Bartoshuk's, recorded right arm flexor and extensor muscle potentials, and also obtained measures of respiration, heart rate and blood-pressure. Highly significant gradients during performance were found in right arm muscles, heart rate and blood-pressure. Those for respiration and forehead muscles were less reliable but significant over a limited number of trials. Significant correlations between steepness of some of the physiological gradients (particularly blood-pressure) and performance time were obtained, the steeper the gradient the shorter the performance time.

Table XI.5 shows the intercorrelations among measures of gradient steepness.

It would seem from these findings that gradients of physiological functions other than skeletal muscles are related to overt performance, and the authors

below it (1950). Stimuli of 1,000 cycle tones, ranging within less than 10 db above and below the usual auditory threshold were used, and it was found that these weak subliminal stimuli produced muscular responses even when the subject thought that he had

TABLE XI.5
INTERCORRELATIONS AMONG MEASURES OF GRADIENT STEEPNESS (N = 43)
(From Malmö and Davis, 1956)

Physiological variable	Trials	Extensor 5-8	Flexor 1-4	Flexor 5-8	Heart rate 1-4	Heart rate 5-8	Blood- pressure 1-4	Blood- pressure 5-8

Extensor muscle . . .	(5-8)		0.38	0.44	0.12	0.32	0.26	0.55
Flexor muscle . . .	(1-4)			0.67	0.02	0.26	0.05	0.34
Flexor muscle . . .	(5-8)				-0.01	0.47	-0.17	0.35
Heart rate . . .	(1-4)					0.53	0.25	0.35
Heart rate . . .	(5-8)						-0.18	0.20
Blood-pressure . . .	(1-4)							0.42

have suggested, on the basis of the significant intercorrelations which were observed, that all these physiological functions may share, at least in part, some of the same mechanisms of central-neural control. They suggested that autonomic gradients may be used along with skeletal muscle gradients to provide a composite measure of arousal.

Adaptation

There is evidence that some kind of adaptation occurs during an experimental session. Davis has found in a large number of experiments that the *level* of tension between responses to stimuli declines through the session, and he has suggested that this diminishing tension might signify the initial presence of a response to the experimental situation which becomes extinguished as the session progresses. A significant decline in right forearm tension (but not in forehead tension) during a ten-minute rest period after connecting subjects to the electrodes has also been reported (Martin, 1956).

Auditory stimuli are known to produce muscular responses. R. C. Davis and his collaborators, in a series of studies (1948*b*, 1950, 1956*a,c*; Davis and Van Liere, 1949; Davis, Buchwald and Frankmann, 1955) have investigated adaptation effects to repeated auditory stimuli of different intensities, and their results will be presented in some detail since these experiments represent one of the best and most systematic attempts to relate response changes to stimulus variation. He has examined the question of how far down the scale of stimulus intensities such responses may be observed, by presenting sounds near the absolute threshold, some above and some

not heard the sound, although responses to unheard stimuli were smaller than to those reported heard.

The effects of various other factors were considered in this study, with the following results—

(i) repeated weak stimulation: a significant *increase* in response to the second stimulus was observed.

(ii) changes in stimulus intensity: responses showed little change with stimulus intensity up to the threshold, but above it they increased rapidly.

The sensitization of response to very weak auditory stimuli is in contrast to the responses to stimuli above 70 db to which varying amounts of adaptation were found (Davis *et al.*, 1955). Habituation appears to be a function of the size of the stimulus; very loud sounds (e.g. gunfire in the Davis and Van Liere, 1949, experiment) may not be followed by successive reduction in the amplitude of the response.

Two effects following strong auditory stimuli have been described by Davis (1948*b*); the *a* response and the *b* response. In this study, sound stimuli of 500 cycles were used at three intensity levels, 90, 95 and 99 db, each lasting four seconds, and recordings were obtained from the extensor muscles on the dorsal surface of both forearms.

The *a* response begins about 0.1–0.2 sec after the onset of the stimulus, reaches its peak about 0.1 sec later, and almost disappears by the next 0.5 sec. The *b* response seems to begin about 0.8 second after the onset of the stimulus, maintains this level for about another second, and then decays, rapidly at first and then slowly. The *a* response was found to show marked adaptation and had practically disappeared

(From Davis, Buchwald and Frankmann, 1955)

after six or so repetitions of the stimulus; it was also affected by the intensity of the stimuli. The *b* responses were not so affected. Pre-stimulus tensions were found to be important both in determining the size and the spatial distribution of the *a* and *b* responses.

In a later experiment (Davis, Buchwald and Frankmann, 1955) a two-second 1,000 cycle tone of varying intensities (70, 90, and 120 db) was presented four times to subjects at one-minute intervals.

FIG. 11.6. MUSCLE-ACTION POTENTIAL (M.A.P.) RESPONSES AND GALVANIC SKIN RESPONSES (G.S.R.) PLOTTED AS A FUNCTION OF INTENSITY OF A 1,000-CYCLE TONE
(From Davis, Buchwald and Frankmann, 1955)

Figs. 11.4 and 11.5 show the responses for right and left forearm to the different intensities of stimulation. (These figures average the readings for all subjects for each measurement before and after the three stimulus intensities). The effects of stimulus intensity are given in Fig. 11.6 in which the *a* and *b* responses, both arms combined, are plotted as a function of stimulus intensity. The curves confirmed previous findings that the *a* response function undergoes a marked acceleration at a stimulus intensity of about

100 db and that the *b* response does not increase so rapidly.

The *a* response is significantly greater to the 120-db stimulus than to either of the two weaker stimuli; the difference between the effects of the weaker stimuli is non-significant. The general conclusions are the same for the *b* response, although the significance levels for the difference between strong and weak stimuli are somewhat lower.

Adaptation effects to the various intensities are seen in Fig. 11.7. For the *a* response, stimulus *A*, there is a significant decrease ($p < 0.01$) from first to last quarter of the sitting. For *B* and *C* stimuli combined, the successive quarters decline, but not significantly. For the *b* response, the slope of the adaptation curve for the strong stimulus is less steep, and the curve for the weaker stimuli follows it more closely. For both types of stimuli the difference between the first and last quarters is significant ($p < 0.05$). "Thus we have the rather complex situation that adaptation is a function of stimulus intensity for the *a* response, whereas for the *b*-response adaptation is less, and is not much affected by stimulus intensity." (Davis *et al.*, 1955.)

High intensity tones—100, 110, 115 and 117 db—of brief duration and presented to the subject at approximately 6-sec intervals, were used in a further experiment recording potentials from forearm muscles (Davis, 1956a). Each of the four stimulus intensities was delivered to each subject four times, in a Latin-square design. A progressive increment of response with increased stimulus intensity was clearly observed in the *a* response, the tension response within the range of stimuli used being approximately in proportion to the decibel level of the stimulus. On this occasion no *b* response was obtained, and Davis attributed its absence to the brevity of the tones used in this experiment (0.2 sec compared with 2.0 and 4.0 secs in the study previously described).

Again, adaptation to all stimulus intensities was apparent, and with its progress the effects of the several intensities remained, about as different from each other as they originally were. Davis (1956a) has summarized the findings on muscle action potentials in relation to auditory stimulation as follows—

- (i) the overall intensity response relation is probably curvilinear and positively accelerated.
- (ii) the persistent effects of noise are probably a prolongation of the *b* response.
- (iii) an instructed movement to a stimulus following quickly after a tension reflex will "reinforce" that reflex and prevent it from adapting.

As mentioned earlier, decline in background tension levels is a feature of all experiments. However, in two studies in which a steady continuous noise

occurred, the level of muscle tension was sustained throughout (Davis, 1956c).

Studies Involving Psychiatric Patients

Several studies designed to objectify patients' complaints of symptoms apparently relating to certain muscle areas have been carried out. Tensional headache is a problem of this kind. Wolff (1948)

FIG. 11.7. ADAPTION OF MUSCLE-ACTION POTENTIAL RESPONSES (*a* and *b*) TO VARIOUS INTENSITIES OF A 1,000-CYCLE TONE PRESENTED IN MIXED ORDER DURING A SITTING

A = 120 db, *B* = 90 db, *C* = 70 db

(From Davis, Buchwald and Frankman, 1955)

believed that head and neck muscles were frequently maintained at high levels of contraction and that this could be a cause of headache and other head sensations. Malmö and Shagass (1949b) showed that headache proneness was associated with increased muscle potentials of the neck during a standardized series of painful stimulations applied to the forehead, but was not associated with high heart rate, high heart-rate variability, or respiratory deviation. They put forward the principle of "symptom specificity" which stated that in psychiatric patients presenting a somatic complaint, the particular physiological mechanism of that complaint is specifically susceptible to activation by stressful experience.

Sainsbury and Gibson (1954) investigated the relation between symptoms reported by psychiatric

patients and the activity of the skeletal muscles, and they also related the electromyographic measurement of skeletal activity from the left forearm and *frontalis* muscles to the patients' scores on an inventory

FIG. 11.8. MEAN CHANGE IN ARM AND NECK TENSION PLOTTED AGAINST INTENSITY OF THERMAL STIMULATON
(From Malmö, Shagass and Davis, 1951)

composed of items such as presence of worry, apprehension, inability to relax, etc. Their results may be summarized as follows—

(i) forehead (*frontalis*) tension; measured during rest, was significantly lower in a group of healthy normals than in a group of anxiety states.

(ii) when the patients were divided into two groups, one scoring high and the other scoring low on the "anxiety" inventory, mean muscle tension of forearm extensor and *frontalis* muscles was found to be significantly higher in the high-scoring group.

(iii) EMG measurements from specific symptom areas—headaches, aching of the arms, stiffness of the neck—were compared in patients with and without the symptoms: in each case there was a

significantly higher tension in the relevant muscle area in patients with the symptom.

(iv) Concurrent recordings were obtained from fifteen patients from *frontalis*, left forearm and left foot extensors, and posterior cervical muscles. A rank correlation of 0.45 was obtained ($p < 0.05$) a result which suggested that there was some degree of generalization of muscle tension.

A series of investigations into the skeletal-muscle response to stress of psychiatric patients has been carried out by Malmö and his colleagues. They have used a wide range of stimulus conditions: pain, administered by means of a Hardy-Wolff thermal stimulator (Malmö and Shagass, 1949a; Malmö, Shagass and Davis, 1951; Malmö and Smith, 1955) sound (Davis, Malmö and Shagass, 1954), perceptual and motor tasks (Malmö, Shagass and Davis, 1951) and psychiatric interview (Malmö, Shagass and Davis, 1950, Davis and Malmö, 1951, Shagass and Malmö, 1954).

Their early studies were prompted by the premise that the distinguishing feature of anxiety is that the patient reacts to ordinary everyday life situations as though they were emergencies. The first of the series (Malmö and Shagass, 1949a) employed a variety of physiological measures, including neck muscle potentials, recorded in association with thermal stimulation. Since anxiety has also been described as the expectation of trauma, recordings were also made during the anticipatory or preparatory phase prior to the application of the stimulus.

It was found that anxiety states and early schizophrenics were the most muscularly tense with the mixed patient group next and controls the lowest in tension. In the 1951 study (Malmö, Shagass, and Davis) EMG recordings were made from seventy-five patients: seventeen chronic schizophrenics, fourteen acute psychotics (mainly schizophrenics), forty-four psychoneurotics with pathological anxiety or tension, and twenty-one controls. Recordings of neck and right forearm flexor muscle potential were made under several conditions: pain stress, rapid discrimination test, and mirror drawing. The general conclusion here was that psychoneurotic and psychotic patients responded to stress with a greater degree of muscle tension than that found in control subjects; this finding was consistent for all the stress situations. Also, the general level of muscle tension was as high in schizophrenics under stress as in other psychiatric patients, except that they were tensionally under-reactive to pain stimuli.

It can be seen from Fig. 11.8 which shows mean change in neck and arm tension plotted against intensity of thermal stimulation that, apart from the arm response of the chronic schizophrenics, the

magnitude of the tension response increased as the stimulus intensity increased. Differences between patients and controls were most pronounced at the lower intensities and were not in fact statistically significant at the higher intensity levels. There was also evidence of a considerable individual consistency from one stress situation to another.

The patients showed a marked overreaction to the instructions in the preparatory period of the mirror drawing task; to account for this and similar results it was suggested that there may be a deficiency in the neurotics' central nervous system regulatory mechanism, such that immediate tensional output is too great.

Malmo and Smith (1955) have since reported further work using the pain stimulation procedures with measures of *frontalis*, neck, left and right forearm flexor and extensor muscles, obtained from a group of mixed patients (mainly anxiety states) and from normal controls. Mean tension values for each pre-stimulus period, warning, stimulation and post-periods were obtained. *Frontalis* muscle tension was found to be consistently successful in differentiating the patient from the control group, but on this occasion neck and forearm muscle potentials were only mildly successful in differentiating the groups.

The studies which have been described have mainly classified the neurotic subjects into two categories: anxiety states and mixed patients. The dimensional analysis of neurotic subgroups made by Eysenck (1952) showed that dysthymics (anxiety states, depressives, obsessional-compulsive states) were significantly differentiated from hysterics on a variety of tests. On this basis, therefore, an experiment was planned to investigate the levels and reactivity of muscle tension in two neurotic groups, one comprising anxiety states, the other mainly hysterics (Martin, 1956). Recordings were obtained from *frontalis* and right forearm extensor muscles during rest, and to various stimuli (delayed feed-back of speech during reading, and a motor frustration task). The anxiety states were significantly differentiated from the hysterics in both muscle areas during rest but not during stimulation. It was predicted that during the initial relaxation period lasting ten minutes differential relaxation rates of normals and neurotics would be observed, but although there was a downward trend in tension scores during the period the slopes of the curves were similar in both groups and failed to discriminate between them.

The electromyographic reaction to strong auditory stimulation was studied in groups of normals and psychiatric patients (ten neurotic and ten acute schizophrenic) by Davis, Malmo and Shagass (1954). Forearm extensor muscle potentials were recorded to ten stimuli (a burst of white noise lasting 0.125 sec

administered at one-minute intervals). Amplitude of responses at each tenth second period were measured for one second before and two seconds following each stimulus. (The curves of patients' and controls' responses are given in Fig. 11.9).

When the relation between background tension and amount of response was taken into account the patients were found to have a significantly higher response at 0.3 sec after stimuli than the controls ($p < 0.05$) and at 0.4 sec the significance of the

FIG. 11.9. COMPARISON OF PATIENTS AND CONTROLS IN FOREARM MUSCLE POTENTIAL AMPLITUDE FOR EACH TENTH-SECOND PRECEDING AND FOLLOWING STIMULATION. Each point on the curve is based on the averaged data from the first four stimulations.

(From Davis, Malmo and Shagass, 1954)

difference increased to the 1 per cent level. The authors considered their results within the framework of the startle pattern described by Landis and Hunt (1939); in the *immediate* reflex action which is of very brief duration there was no significant patient-control difference, but a delayed elevation of tension was observed in the patient group in the secondary or after-response. It would be of interest to repeat this study with a more homogeneous group of patients and with measurements from other muscle areas.

Marked adaptation of the response occurred in both psychiatric and normal groups. Adaptation effects in patients were also studied by Malmo and Wallerstein (1955) to a series of ten 3-sec heat stimulations applied to the forehead at 1-min intervals. The right forefinger rested on a button which the subject was instructed to press when he felt the heat was about to become painful (although it was explained that the pressure on the button would not terminate the stimulus).

Although a falling tension in the control subjects throughout the ten stimuli was noted, in contrast to

the steady tension level maintained by the patients, the differences between the groups were not statistically significant. The patients significantly differed from the controls in the amount of change of mean latency of button pressure throughout the series (controls showed increased latency) and also in change of duration of button pressure, controls showing decreased durations. The results were interpreted as supporting the hypothesis that neurotics show less decrement in the strength of a voluntary response as a function of its repeated elicitation.

The Interrelationships of Tension Measures

When rather different motor tests are used, correlations appear to be quite low. However, if the clinical picture of generalized tension in certain psychiatric patients is correct, correlations between muscle areas measured electromyographically should be reasonably high.

As described earlier, Sainsbury and Gibson (1954) obtained a significant coefficient of concordance from four groups of muscles. This finding suggested that an increase of bodily tension in one area is reliably associated with an increase in other areas, but it should be noted that in this study selected anxious and tense patients were seen whose symptoms were probably rather severe.

A more extensive analysis of interrelationships was carried out by Malmö and Smith (1955) who factor-analysed ten variables: six were direct measures of muscle tension, from forehead, neck, left and right forearm extensor and flexor muscles, and the other four measures were EMG fluctuation, finger movement irregularity, head movement and body movement.

No factor of generalized muscle tension appeared; five of the muscle tension measures fell into a single factor of neck and bilateral-forearm tension while the

sixth, *frontalis*, grouped itself with measures of movement and irregularity.

Summary: Muscle-action Potentials

1. *General conclusions.* All reported stimulus-induced changes have been an increase in muscle-potential; size of the response may depend upon pre-stimulus levels.

Adaptation of background tension levels throughout experiments is frequently observed, and the muscle-action potential response in general adapts quickly to repeated auditory stimuli. At extremes of stimulation R. C. Davis has reported increasing reaction to sounds near the auditory threshold, but little adaptation to sounds of very high intensity.

The response also increases as a function of increasing stimulus intensity: the overall intensity response relation is probably curvilinear and positively accelerated.

Latency is short (approximately 0.01 sec) and the response (Davis's *a* response) reaches a maximum within 1 sec following the stimulus.

2. *In relation to psychiatric disorder.* Most of the studies on psychiatric patients agree in one respect: that anxious patients demonstrate a *higher* level of muscle tension than normals. This seems to be consistently reported of *frontalis* muscles, and to a less extent with forearm and neck muscles. There is less information about the precise conditions under which the findings hold but there is agreement that the *frontalis* difference is apparent during rest (in anxious patients compared with controls) and also that forearm and neck muscle responses are slightly greater to certain forms of sensory stimulation, e.g. pain.

Strong auditory stimuli in one study also produced tensional responses of higher amplitude in a group of mixed psychiatric patients.

CENTRAL MECHANISMS

Many hypotheses may be found in the psychological literature concerning apparently central effects on the somatic responses which have been considered in the previous sections. Efforts are frequently made to underpin theoretical postulates (e.g. of the type that neurotics manifest a failure to adapt or a tendency to overreact) with reference to an assumed deficiency of functioning of some central regulatory mechanism such as the hypothalamus, the cortex, or the reticular activating system.

At the present time it is impossible to attribute either those aspects of total behaviour labelled "emotional," or particular somatic response functions, to any single central mechanism. Almost any kind of

response is undoubtedly integrated from a number of different levels in the hierarchical arrangement, and the precise manner in which these centres interact and their relative contributions to the final response are largely unknown. The present section will give an idea of the sort of research which has been carried out with these problems in mind.

The assessment of behaviour consequences of central electrical stimulation or experimental ablation is frequently made by means of observations of total behavioural patterns such as "rage." The interpretation of such results is at best only suggestive (see Chapter 14 by Victor Meyer for a criticism of these techniques and experimental reports). Another more

precise means is to record peripheral autonomic and skeletal muscle activity, although it has already been mentioned that these responses bear no clear-cut relationship in humans to different emotional states, and to infer the presence of an emotion from physiological arousal may not be justified. It would be more accurate, especially in studies with human subjects, to give results simply in terms of amplitudes and latencies of somatic responses (or other measurable responses).

The localization of function frequently attempted in experimental work employing techniques of electrical stimulation and ablation is a highly doubtful procedure (cf. Chapter 14) but some of the findings of this type of work may provide interesting clues for further investigation.

It has been found with lower animals (cats in particular have been studied) that decortication does not eliminate emotional expression; in fact decorticated animals respond rather readily and violently to rage-provoking stimuli. Such exaggerated responses, it has been suggested, result from the release of lower centres from cortical inhibition. Decerebration, however, is followed by a severe reduction in responsiveness.

Systematic exploration of the hypothalamus by means of electrical stimulation has shown that rage reactions, involving autonomic-somatic discharge, can be produced; the reaction usually ceases with cessation of the stimulus (but *see also* Hess, 1954). Bard (1934) found that animals with cortex and thalamus removed still showed rage if only the posterior part of the hypothalamus was left, but if the hypothalamus was completely removed the integrated rage pattern did not develop. (*See* Lindsley in *Handbook of Experimental Psychology*, p. 492, 1951, and Gellhorn, 1953, for discussions of this work.) Facts of this kind have emphasized the importance of subcortical mechanisms in the integration of emotional expression and in controlling autonomic reactions.

The careful work of Ranson (1937) and Hess (1954) using point by point stimulation of diencephalic regions with deeply embedded electrodes in freely-moving unanaesthetized cats, has furthered our understanding of the organization of autonomic and motor effects within the diencephalon. Hess's conclusions were that stimulation of the middle and posterior part of the diencephalon produces an effect of *general* sympathetic nervous system excitation, such as Cannon had described, in conditions of fear and rage. The rostral part of the hypothalamus, on the other hand, was found to be more intimately related to trophic processes such as digestion and elimination, via parasympathetic nervous mediation, and in this zone the arrangement is such that definite

mechanisms, e.g. lapping, vomiting, or defaecation, are evoked by the individual stimuli.

Not only autonomic effects but associated somato-motor signs appear to be mediated by the diencephalon. The distinction between autonomic and skeletal muscle systems, so clear at the peripheral level, is no longer maintained at the diencephalic level, where, Hess repeatedly emphasizes, organization is in *functional* rather than anatomical terms. He conceives of the diencephalon as co-ordinating many activities and functions in which autonomic organs are associated with somatomotor patterns, for example the assumption by the animal of the appropriate posture for defaecation and micturition, in which the functions of individual effector organs are united for the performance of a definite task. This functional integration of different organs and systems may be demonstrated *at all levels* of the nervous system.

The Cortex and Autonomic Functions

There is ample evidence of cortical autonomic representation (*see* Fulton, 1950; Gellhorn, 1953). Certain parts of the cerebral cortex appear to subserve both visceral and somatic functions (Kuntz, 1953; Gellhorn, 1953). This representation, in widespread cortical areas, permits of a functional grouping of autonomic processes to a greater extent than is possible in the hypothalamus and medulla (Hess, 1954). Examples are the sweating response of the palms following stimulation of the cortical motor area of the hand, the lachrymatory and pupillary changes which may follow the stimulation of the somatic cortical representation of eye movement (Kennard, 1947). Other cortical areas appear to be more concerned with visceral functions; these include among others the hippocampus, the amygdaloid area, and the rostral portion of the temporal lobe (Kuntz, 1953).

The relationship of cortex to diencephalon should be of great theoretical interest. Kuntz (1953) quotes experimental data in support of the assumption that interruption of the cortico-diencephalic fibre connexions liberates the subcortical emotional mechanisms from the inhibitory influences of cortical origin. It seems to be widely agreed that hypothalamic areas have the capacity for co-ordinating emotional and autonomic activity independently of impulses arising from the cerebral cortex.

Bard and Mountcastle (1948) found that removal of the neo-cortex leads to a state of "placidity": "in our placid cats the amygdala, the hippocampal formation, and the cortical field of the pyriform lobe had been left intact." When the amygdala and pyriform lobe were removed, a state of ferocity followed. These experiments seemed to indicate that the restraining influence on the hypothalamus is exerted in the cat through the phylogenetically oldest

parts of the cortex (rhinencephalon) and their action opposed to that exerted by the neocortex (a conclusion which cannot be generalized to all species, *see* Fulton, 1950). More recent studies along these lines have been reviewed by Jasper, Gloor and Milner (1956).

FIG. 11.10. SCHEMATIC REPRESENTATION OF PRINCIPAL CENTRAL NERVOUS STRUCTURES AND PROBABLE PATHWAYS INVOLVED IN EMOTIONAL BEHAVIOUR

The diagram does not include the cerebellum and certain basal ganglia that may also participate.

Key. 1—somatic and cranial afferents; 1'—direct thalamocortical projections; 2—visceral afferent pathways; 3—centripetal projections of reticular formation; 4—diffuse thalamocortical projections; 5 and 6—interconnexions of hypothalamus and thalamus; 7 and 8—interconnexions between thalamus and cortex; 9—intrathalamic connexions; 10—intracortical connexions; 11—corticothalamohypothalamic pathways; 12—visceral efferent pathways; 13—hypothalamohypophyseal tract; 14—corticospinal pathways.

The crosshatched area represents the reticular formation.

(From Lindsley, 1951)

Lindsley (1951) and Jasper, Gloor and Milner (1956) have discussed the relationship of the limbic system to subcortical structures, including the hypothalamus; Maclean (1954) believes that this part of the primitive forebrain may provide a mechanism for the elaboration of emotions and emotional expression. Afferent connexions from the vagus to the anterior part of the formation have been demonstrated, and Maclean suggests that in this part of the brain there is a phylogenetically old cortical screen on which may be projected and fused a wide variety

of experiences derived from the visceral and external environment of the organism.

Some findings have recently been reported in connexion with the limbic system as a "reward" system. When rats with implanted electrodes were able to stimulate their own brains electrically by depressing a lever, "rewarding effects" (measured by the time spent pressing the lever) were observed. These rewarding effects were found in only particular areas of the limbic system (Olds, 1955).

Gellhorn (1953) has discussed the role of the cortex with respect to autonomic functions, and has suggested that—

(i) it inhibits autonomic centres, therefore its absence accounts for autonomic hyperactivity in sham rage.

(ii) it provides for a functional association of certain motor with appropriate autonomic effects.

(iii) it makes the activation of the autonomic centres in the hypothalamus possible through impulses reaching the brain via distance receptors of the visual, auditory, or olfactory apparatus. The biological significance of this process is obvious.

On the other hand it has been argued that the cortex plays an excitatory role in emotions and that this hypothesis could account for the reduction of anxiety after prefrontal lobotomy (Arnold, 1955). The general evidence from surgical cases, ablation experiments and local stimulation is that the cortex has both inhibitory and facilitatory effects upon diencephalic structures, and, as Gellhorn (1953) comments, while emotional response in man may be due to cortical excitation it is at the same time true that conditions leading to diminished (but not extinguished) cortical activity seem to predispose to emotional excitement.

Facts concerning the interaction of the cerebral cortex with subcortical structures, together with data from EEG recordings, have led Lindsley (1951) to propose an "activation theory" of emotion. EEG studies have shown that in relaxed individuals with no special stimulation, the dominant activity is the fairly rhythmic 10-per second alpha rhythm. They have also shown that an unexpected stimulus such as a light or a sound will block the alpha rhythm but that upon repetition of the stimulus adaptation will occur. The initial effectiveness of a stimulus in blocking the alpha rhythm thus appears to be its "arousal" aspect, and Lindsley considers the low-amplitude alpha waves of anxious subjects to be akin to this "activation" or "arousal" effect.

Fig. 11.10 illustrates the principal structures and interconnexions which are believed to be involved in the central regulation of emotional behaviour, and Lindsley argues that through these mechanisms varying degrees and complexity of activation are

possible as a hierarchy of reflex responses progressively involves higher levels of the neuraxis.

Experiments with human subjects designed to elucidate the effects of various central mechanisms are hindered on several counts. Firstly, the relationship between somatic responses and "emotions" is not clear enough to allow any peripheral response to be indicative of emotional arousal. Secondly, there is so little knowledge about the behaviour of autonomic and motor responses as functions of stimulus variation that it is impossible to predict how normal response curves might be altered by central abnormalities.

The cortex and hypothalamus feature so prominently in discussions of both "emotions" and autonomic responses that one of the major problems awaiting attention is that of the relative contributions of these regions to psychological and psychophysiological functions. Although in lower animals the removal of certain cerebral areas may produce profound behavioural changes there is little evidence of

clear-cut effects following brain damage in man. This may be due to the fact that analysis of quantitative alterations in specific functions has been neglected in favour of the examination of highly complex "qualitative" behavioural changes. The simultaneous advancement of both physiological and psychological knowledge should provide the material for an interaction of immense promise; what is required from the physiologist is an elucidation of the normal interrelationships of higher nervous mechanisms and more facts about the temporal and spatial effects of agents (such as drugs) which have a depressant or stimulant action on the central nervous system. Psychologists have still to determine more precisely normal behavioural response curves, for example those of adaptation, intensity functions, conditioning and learning. There can be no hard and fast division of labour between the two disciplines. The integration of fact and theory from both will almost inevitably be the outcome of common and frequently joint research effort.

SYNTHESIS AND CONCLUSIONS

The next important task of this chapter is to orientate these experimental data within the wider framework of psychological theory, but before attempting this there are several features which should be emphasized.

First, and of great importance, is the fact that few of the experiments have been repeated; and moreover, even the few repetitions do not invariably support earlier findings. There are three main hindrances to precise replication of the data: (i) the complex (and often highly specific) nature of the *stimuli* employed, (ii) the *measurements* ascertained, which are frequently derived in different ways and may be highly specific to the data, and (iii) the inadequacy of most measures or ratings which form the basis of the selection and grouping of *subjects*.

The unreliability of the measures of somatic systems may reflect the complexity of the physiological mechanisms underlying the functions being recorded but it may also indicate a poor specification of the conditions under which the measurements were obtained, and inadequate instrumentation, techniques and procedures. Such details have been discussed earlier in this chapter because in the absence of general concordance on these points they represent an important, time-consuming part of any experimental study.

The significance of the experimental data on somatic responses to psychology can now be considered in relation to classifications and theories which have already been formulated. The mutual benefit to theory and experimentation which would accrue from the forging of close links between them needs no

emphasis. What is urgently required in much of the experimental work in psychophysiology is guidance and purpose; equally, most existing theories are sadly lacking in support from available facts.

Emotions. Sufficient has been said to indicate that the attempt to fit certain responses to particular emotions is, in the absence of any adequate definition of the emotion, fruitless from an experimental point of view. The individual's assessment of a feeling and the complex nature of the stimuli designed to arouse it are not easily brought within experimental control.

Physiological systems. The arguments against classifications based on the morphologic differentiation of nerves, e.g. sympathetic-parasympathetic systems, have been put forward. Some of the variables, e.g. skin resistance and peripheral vasomotor changes have been regarded as relatively uncomplicated indications of sympathetic activity, but even these are affected by many agents, and frequently sympathetic, parasympathetic and endocrine effects all combine and interact to produce an observed response.

Arousal theories, e.g. the continuum of "energy mobilization" proposed by Duffy (1951). The use of physiological measures which may serve as indicators of the intensity dimension, or "behavioural arousal" has recently been discussed by Malmö (1957) and he has extended this concept to integrate the results of investigations into pathological anxiety in psychiatric patients.

It would hardly be questioned that certain physiological variables do closely reflect the activity level of

the organism, since lowered physiological levels during sleep and high levels during muscular activity have been repeatedly demonstrated. The attempt to differentiate anxious from non-anxious subjects on the basis of greater arousal in the former appears to be partly a restatement of the implicit assumption or hypothesis underlying most experiments which have already been carried out, although it proposes to extend the range of experimental *conditions*, e.g. from sleep to high arousal, under which measurements are obtained. In view of the rather moderate success of a large number of studies which have attempted to discriminate between anxious and non-anxious subjects on the basis of peripheral measures of autonomic and muscular activity it seems inappropriate to be too optimistic about the general importance of peripheral measures in the "anxiety" of man.¹

Malmö has, however, drawn a distinction between pathological and transient states of anxiety, and it is possible that a great deal of the research which has been covered in the present review has failed to make such a distinction. He has suggested that, in *pathological* anxiety, some central inhibitory mechanism may be weakened such that stimulating situations will maintain constantly high physiological levels in the anxious subject. Anxiety is considered as a "disease of over arousal," and the critical neural change is thought of as being produced "by a process of attrition from excessive and extended overarousal" (Malmö, 1957).

The investigation of performance and response curves during different levels of physiological arousal is a most promising line of research, and the results of such studies should provide data of great value and interest.

The dimensional analysis of behaviour as carried out by Eysenck (1952). Eysenck has made certain suggestions concerning the underlying mechanism of the dimensions of "neuroticism" and "introversion-extraversion" which can usefully be considered in this context. He claims that neurotics as a group demonstrate over-reactivity of the sympathetic division of the A.N.S. in response to stressful stimuli, but that introverts and extraverts are characterized by the ease and difficulty respectively with which they form conditioned responses. An explanatory concept of inhibition-excitation has been put forward by Eysenck to account for the behaviour of introverts and extraverts, and the evidence for his proposals discussed in *The Dynamics of Anxiety and Hysteria* (Eysenck, 1957).

The inhibitory concept is defined in behavioural,

rather than precise physiological terms, but the inhibitory-excitatory function of the cortex has been suggested as a likely central mechanism to integrate such widespread responses as conditioned, learned, and perceptual responses. There is evidence that the cortex does in fact influence somatic and autonomic functions, although there are few experimental data on the quantitative effects.

The results of investigations into physiological responses in psychiatric patients have already been summarized, and in general it can be concluded that few convincing and corroborated data have emerged. The exceptions are a consistently high level of muscle action potentials (particularly of the *frontalis* muscles) and a greater degree of vasoconstriction in anxious patients than in normals. These findings have been demonstrated during relaxation and sleep and also in response to certain sensory stimuli. There is also, perhaps, some evidence that blood-pressure is elevated under certain conditions in anxiety states.

In so far as there is evidence of *increased* physiological activity in anxious patients there may be support for the thesis of a greater excitatory potential (or weakened inhibitory potential) in these subjects. The data on hysterics are very few, but there are reports of lower muscle-action potential and greater vasodilatation in this group.

Explanatory hypotheses which incorporate the notion of inhibitory-excitatory mechanisms undoubtedly help to organize the unsystematic and uncoordinated findings; nevertheless, they suffer from the defect that they cannot bridge the gap between integrating diverse findings and offering reasonably precise guidance about what to expect of specific behavioural responses under specific experimental stimulus conditions. It is difficult, in these circumstances, not to agree with the rather empirical outlook expressed by R. C. Davis who has stressed the need which exists at the present to establish further facts simply about how various somatic responses are modified by stimulus variation. The extent to which these S-R relationships are affected by central mechanisms of inhibition-excitation would link this more empirical approach with the theoretical proposals of Eysenck and Malmö.

It has been strongly suggested that a fundamental experimental approach would *begin* with the analysis of characteristic response functions, and that existing categories such as "emotion" are of less value for the purpose of delineating classes of responses than some basic classification of the responses derived from experimental data. There is, of course, no reason why operational definitions (e.g. that of anxiety as the conditioned form of the pain-fear response) should not provide a useful conceptual framework. It is simply the case that, in the absence of experimental

¹ There is evidence (at least in dogs) that peripheral autonomic nerves can be blocked without drastically altering behaviour assumed to relate to anxiety (Wynne and Solomon, 1955). See also Cannon's discussion, *Bodily Changes in Pain, Hunger, Fear, and Rage*, Chap. 19 on the role of the viscera in emotional experience.

data on the concomitant autonomic and somatic responses such definitions can be only of potential value.

Learning theory. A great deal of experimental work has been carried out using various indices of "anxiety" in relation to conditioning and learning. Although Solomon and Brush (1956) have admitted that anxiety theories leave many questions open for investigation they maintain that avoidance of strong or noxious stimuli is of great interest because (among other reasons): "The emotion and motivation theorist sees the fear and anxiety concomitants—of avoidance behaviour as possibly relatable to complex emotional disturbances in human subjects."

Although certain peripheral A.N.S. responses are considered to indicate a state of anxiety, there is evidence that the blocking of peripheral A.N.S. activity of dogs (Wynne and Solomon, 1955) and adrenalectomy in rats (Applezweig and Bawdry, 1955) do not eliminate escape and avoidance learning although it may be retarded. Solomon and Brush (1956) have proposed an ingenious explanation of findings such as these: they have suggested that the stimulus pattern from the viscera may serve as an important aversive stimulus pattern (drive) in its own right *early* in training: "Later on, when the avoidance response is quick, not so much goes on in the way of peripheral A.N.S. responding (the anxiety conservation principle)¹ but the reinforcing properties of proprioceptive stimuli and C.S. termination now are very important."

There has always been a traditional distinction between the categories of learning and emotion, but it would be argued today that there is no real justification for this. Malmo has recently made the proposal that measures of physiological activity may be usefully employed in the assessment of drive level (Malmo, 1958), and the general activity of the system being conditioned is a very important factor in the ease or difficulty with which conditioning is achieved (Martin, 1960).

Further, there is no basic division between the conditioning process and the phenomena of adaptation and disinhibition which have been discussed in the present chapter: they are all important functions which reflect changes in the C.N.S. to stimulus variation. Any theory which aims to account for these changes is likely to use familiar terms such as drive or arousal level, reactive inhibition, response strength, response latency and reaction threshold—concepts which may profitably be anchored to measurements of somatic responses.

The discussion so far has been based largely on reactions to sensory stimuli, as the simplest case to start with, although even in the case of these relatively

simple stimuli the facts (concerning the responses obtained) are not clear. It is apparent that some qualitatively different stimuli produce reactions more readily than others, and the pattern of the response may differ with the modality of the stimulus employed.

It seems likely that it will be necessary at some time to study the responses which are provoked by *complex* stimulus constellations, not so much because of the sensory attributes of such stimuli but because of the specific significance attached to them by the individual.

In the case of sensory physiology and visual psychophysics the traditional approach has been to work with simple stimuli, the characteristics of which can be specified in terms of physical dimensions (e.g. wave length) and to understand complex functions in terms of what is known about the simple (*see* Chapter 4). This principle almost certainly can fruitfully be applied to the study of autonomic and muscular responses, and indeed there is scattered evidence about the differential reactivity of neurotics to simple sensory stimuli of sound and pain, and of schizophrenics to heat and cold stimulation, which suggests that promising results can be expected from this type of research.

This molecular approach does not, of course, preclude the molar one which seeks to relate complex stimulus constellations to measurable responses: they are mutually supporting rather than mutually exclusive. For example, "lie-detection," claimed by many to have immediate practical usefulness, depends upon the effect of complex stimulus conditions upon measures such as the G.S.R., heart rate and blood-pressure. In this case the immediate usefulness of the technique is undoubtedly related to the significance of the stimulus words. Again, certain test scores may differentiate groups of subjects (e.g. neurotics from normals, cf. the work of Wenger) and so have diagnostic value, or they may predict success and failure at particular jobs.

Promising tests may be discovered without prior analysis of the responses, but, as Eysenck (1952) points out, the responses must subsequently be experimentally analysed, purified, and the new measures used to isolate the relevant factors with greater accuracy.

The biological significance of many of the reactions to simple sensory stimuli remains unclear, but such stimuli have widespread somatic effects which obviously alert the organism, and which may facilitate performance. Many of the general arousing responses show rapid adaptation, while other, more segmental, reflexes are highly resistant to adaptation.

The avoidance reaction set up by stimuli of high intensity is of more evident biological utility. These traumatic stimuli might produce effects of a very different kind (a true "emergency" reaction to avoid tissue damage) from those of more mild stimulation:

¹ See Chapter 13 of this HANDBOOK by Gwynne Jones.

there is evidence, for example, that such responses are more resistant to adaptation, and that even the anticipation of strong stimuli might be accompanied by measurable somatic reactions.

There are several hypotheses dealing with the reactions to less than traumatic stimuli. Their "arousal" or "alerting" value has been recognized. As Ackner (1956) has pointed out, in the case of sensory stimuli sensation *per se* is not the cause of the vasoconstrictor response; a cold stimulus does not maintain vasoconstriction, although it may be continuously recognized as cold.

Ackner's view that the vasoconstrictor response is part of an arousal or alerting reaction to a new stimulus situation is closely paralleled by the statements of Sokolov (1957) on what is termed the "orienting reflex." This author, using measures of skin resistance, plethysmograph, and the EEG, has measured changes produced by auditory, visual, tactile, thermal, proprioceptive and pain stimuli of varying intensity, duration and quality. In his discussion of the reaction obtained (the "orienting reflex") he comments: "The essential proof of the orienting nature of these reactions is the fact that they arise in response to every change in the environment, whether the stimulus is switched on or off, increased or decreased, or qualitatively changed."

It has been postulated (Milerian, 1957) that the cortex exercises an essential regulatory influence on the orienting reflex, inhibiting reflexes to stimuli which have no biological significance for the organism; although the physiological mechanisms of the orienting reflex are localized in subcortical centres, its normal function depends upon the interaction of cortex with subcortex.

It has frequently been claimed that the size of a response reflects differences in the conscious assessment of the significance of the stimulus, but in general it has proved difficult to relate different forms of responses to subjective assessments (particularly concerning "feelings") although some success has been claimed concerning degree of interest (Wallerstein, 1954) task difficulty (Davis, 1938) and, as would be expected, between judgements of intensity of stimuli and amplitudes of somatic responses.

Somatic responses may also be related to the quality of performance of certain tasks; it has been shown, for example, how gradients of muscular and other responses may be related to a measure of good performance, and Davis (1956b) has argued that overt responses may be influenced by the amplitude and distribution of pre-performance muscular tensions. The results of experiments dealing with quality or type of certain movements may, therefore, be partially understood in terms of the underlying physiological pattern.

The shape of this chapter has been dictated to a large extent by the paucity of explanatory concepts in a field abundant in detail: it has been guided by the purpose of presenting the available data on functional relationships between quantified stimuli and measurable somatic responses. So much has been done by so many investigators that the almost total lack of replication is not only a hindrance to the integration of "fact" into general theory but itself indicates the task for future research. The stage has been reached where the need for clearly formulated aims, and painstaking check and countercheck of experimental results, is paramount.

CHAPTER 12

Conditioning and Abnormal Behaviour

CYRIL M. FRANKS

INTRODUCTION

DESPITE half a century of experimental investigation and remarkable advances in laboratory technology there is as yet little agreement concerning the relative influences and importance of such fundamental parameters of the conditioning process as the intensity of the unconditioned stimulus or the relationship between conditionability and age. Furthermore, neither the neurophysiological mechanisms by which a conditioned response is established, nor even the site or sites of action have been determined with any degrees of confidence. It is not known whether it is meaningful to use the term "conditionability" at all with reference to any individual or animal, and the existence of a general factor remains yet to be demonstrated. There is little agreement concerning the delimitation of the term *conditioned response*, or what aspects of behaviour should be included in this category. For example, Konorski (1948) includes both classical and instrumental conditioning, whereas Thorpe (1956) limits his definition to the classical or Pavlovian variety. Bearing this situation in mind

and the fact that there is no universally recognized theory of learning, it is hardly surprising that the relationship between conditioning and learning is a matter of controversy and that no adequate or generally accepted theory of conditioning has yet emerged.

The primary purpose of this chapter is not to review such problems (this has been done elsewhere, Franks, 1958*b*), but to attempt an integration of a series of laboratory experiments into a theory of conditioning as it relates to personality and, in particular, as it relates to the aetiology, diagnosis and treatment of certain psychiatric abnormalities. The orientation of the author may be described as operational behaviourism; on the conditioning side, instigated by the vague and often internally inconsistent concepts of Pavlov and by the more precisely formulated, but also sometimes inconsistent, postulates of Hull; on the personality side, making considerable use of the dimensional system as described by Eysenck and his associates.

CONDITIONING AND PERSONALITY: DEVELOPMENT OF A THEORY

Previous Investigations

Before presenting a consistent theory of conditioning and personality it will be salutary to consider briefly the chaotic scene. In one form or another almost every aspect of temperament and mental abnormality has been presented as a consequence or malfunction of some conditioned response mechanism. For example, Freeman (1948) tried to treat negative adaptation in life situations as a kind of inhibitory conditioning and positive adaptation as a form of facilitatory conditioning, while Lovell and Morgan (1953) have managed to account for the development of a complex in similar terms. Murphy (1947) has even explained such deep-rooted personality traits as thrift as a result of conditioning, making use of an elaborate

system in which two processes, canalization and conditioning, account for all learned action patterns.

Gantt (1953*b*) has tried to formulate the principles that precipitate a neurotic breakdown in terms of a cleavage or dysfunction between the emotional, visceral and motor conditioned responses, while Liddell (1950) believes that the "choice" of neurotic breakdown induced in his animals is independent of breed or temperament. He believes that the intertrial intervals in the conditioning situation are the deciding factors; thus short intertrial intervals produced tonic immobility in his goats, whereas long intertrial intervals produced a chronic state of agitation or hyperexcitability. From these data Liddell somewhat vaguely speculated that the choice of neurosis is a

function of certain time constants in the central nervous system. Laughlin (1956) interprets adult neurosis as a product of earlier traumatic conditioning in childhood in a manner not too different from the psychoanalytic concept of the origins of traumatic neurosis, while Stogdill (1934) has made an interesting, but unfortunately largely anecdotal, attempt to formulate a theory of neurosis based almost entirely on learning and conditioning.

However, the conditioned response theory of neuroses which has the most influence on psychiatric thinking is undoubtedly that of Pavlov (1927, 1928, 1941, 1951, 1955), whose system is too well known to require elaboration here and, in any case, is too internally inconsistent and complex to describe in a few summary statements. Using one or more variations of Pavlov's techniques, experimental "neuroses" have been induced in all kinds of animals by numerous workers and it is remarkable how closely the abnormal behaviour symptoms induced artificially in animals resemble those obtaining in the neurotic human (e.g. Anderson and Liddell, 1935; Gordon, 1948; Liddell, 1956). It is of more relevant interest that similar techniques are also effective in producing experimental neuroses in humans (Freeman, 1940; Krasnogorski, 1925). (cf. Chapter 19 of this HANDBOOK by P. Broadhurst.)

One consequence of the inextricable confusion permeating Pavlov's writings, as presented in the English language, is the emergence of numerous and sometimes conflicting psychiatric systems supposed to be largely based on Pavlovian psychology. Of these probably the most well known, outside the Soviet Union, are Salter's desultory and superficial excitation theory (1949), Wolpe's reciprocal condition inhibition theory (1954), and, more recently, Sargant's (1957) admirable, if limited, extension to the treatment of various forms of war neuroses and the mechanics of political indoctrination and "brain-washing."

Of these three variations that of Wolpe is the least unsatisfactory. He regards neurotic behaviour as persistent, unadaptive conditioned or learned behaviour in which anxiety is almost always prominent; he presents considerable supporting evidence for his theory, and, unlike many psychiatrists, he is careful to state what he means by "anxiety." According to Wolpe, successful therapy depends upon the successful inhibition of these learned neurotic response patterns, and he presents detailed descriptions of the techniques by means of which this situation may be brought about. Like Dollard and Miller (1950), Wolpe leans heavily on Hullian learning theory but differs from these authors in several important respects. First, unlike Dollard and Miller, Wolpe does not accept the psychoanalytic account of what is supposed to happen to the patient during therapy. Second, he does not

regard extinction as the main mechanism by means of which neurotic habits may be eliminated. Wolpe parts company with the more conventional Pavlovian therapists in his rejection of straightforward protective inhibition as a major therapeutic device. In its place he substitutes a complex and not very clear concept of reciprocal conditioned inhibition which is supposed to be the basis of most fundamental psychotherapeutic effects (cf. Chapter 20 of this HANDBOOK by H. Gwynne Jones).

It might be imagined that one essential prerequisite to the development of any conditioned response theory of personality and mental abnormality would be a detailed examination of the conditionability of various personality types and neurotic subgroups. Individual differences in conditionability have long been observed and there have been some attempts to describe different types of people according to the way they form conditioned responses, these experiments being carried out mainly with normal children (Cowan and Foulke, 1934; Ivanov-Smolensky, 1927a; Osipova, 1926; Pen, 1933). James (1934) differentiated twenty dogs into excitable and inhibitable types on the basis of their behaviour during the establishment of conditioned salivary discrimination. He believed that there must be a correlation between morphological form and behaviour type. In a similar manner Marinesco and Kreindler (1934), following Kretschmer's classification, noted corresponding patterns of conditioned response behaviour in children. But, with the exception of the anxious subject, remarkably few studies have been made of particular personality subgroups, and most investigators have confined themselves to the analysis of the conditionability of neurotics as a unitary group. This extensive concentration on studies of anxious states is possibly attributable to the ready availability of anxious individuals, both inside and outside psychiatric institutions, and also to the widespread interest which the problem of anxiety engenders both in clinical and research circles.

With the exception of Darrow and Heath (1932), who found no consistent relationship between neuroticism as measured by a personality questionnaire and P.G.R. conditionability, most investigators report that neurotic patients condition more readily and more strongly than normal subjects (e.g. Finesinger, Sutherland and McGuire, 1942; Fink, 1943; Schilder, 1929). Spence and Taylor (1952) compared eyeblink conditioning in normal, neurotic and psychotic subjects, predicting that because of the greater manifest anxiety both neurotics and psychotics would condition more easily than normals. However, they found that although the psychotics conditioned significantly more easily than the other two groups, the neurotic and normal groups differed insignificantly.

It is important to note that they neither related the amount of conditioning to the diagnosis of their neurotics, nor even stated what kinds of neurotics were included in their sample. A probable explanation of the finding that, in most, but not all, studies of conditioning in neurotics, the neurotics were found to condition more readily than normals will be offered shortly.

One of the few relevant facts that seem to be well established is that anxious subjects condition more easily than those who are relatively non-anxious. Welch (1953), in his review, concludes that pathological anxiety tends to produce more rapid conditioning and more slow extinction. This has been demonstrated for the P.G.R. (e.g. Schiff, Dougan and Welch, 1949; Welch and Kubis, 1947*a*, 1947*b*) and for the conditioned eyeblink response (e.g. Hilgard, Jones and Kaplan, 1951; Spence and Farber, 1953; Spence and Taylor, 1951; Taylor, 1951). The precise relationship between anxiety and conditioning apparently depends, among other things, on the measure of anxiety used. Thus Berry and Martin (1957) found no relationship between P.G.R. conditioning and the Sarason Test Anxiety Scale, whereas Welch and his associates found a positive relationship when clinical criteria were used to measure anxiety (Schiff, Dougan and Welch, 1949; Welch and Kubis, 1947*a*, 1947*b*).

The development of a reliable measure of individual differences in anxiety is of both practical and theoretical importance. One difficulty, as Kamin (1957) points out, is that the kind of threat manipulatable by experimentation and the anxiety of psychiatric patients may be mutually irrelevant. Jenkins and Lykken (1957) present further objections to the unitary concept of anxiety and there is little doubt that anxiety is a concept which is essentially further resolvable (Franks, 1956*c*).

Of the many attempts to provide objective measures of anxiety, reviewed elsewhere (Franks, 1956*c*), Taylor's scale is the best known. Taylor herself (1956) provides a recent review of the many uses of her scale, especially in relation to Hullian drive theory. In particular, her scale has been used by Spence and his associates to make predictions about eyelid conditioning. Working within a Hullian framework, in which behaviour is supposed to be a multiplicative function of a learning variable (${}_sH_R$) and a motivational or drive variable (D), they have made certain predictions concerning the conditionability of anxious subjects. Arguing that total effective drive strength is, in part, a function of the manifest anxiety of the individual, they assume, like Miller (1948) and Mowrer (1939), that anxious subjects have a higher drive than less anxious subjects. Hence Spence and Taylor predicted that subjects scoring high on Taylor's Scale would

condition more readily than subjects who obtain only low scores (Farber and Spence, 1953; Spence and Farber, 1953; Spence and Taylor, 1951; Taylor, 1951; Spence, 1956).

In general their findings support this prediction, although the relationship obtained was often tenuous and sometimes even insignificant. Furthermore, in many cases this relationship became apparent only when extreme groups were compared. Nevertheless, despite these confusing and apparently conflicting results, there is adequate reason to assume that a positive relationship between anxiety and conditioning does exist. Some of this confusion, for example the occasional poor results of Spence and his colleagues, will become understandable at a later stage in this chapter.

Apart from the anxiety states, little attention has been paid to other kinds of neurotics. It is a remarkable fact that, although the aetiology of treatment of the hysterical disorders has evoked considerable attention from peripatetic psychiatrists interested in conditioning theory, the fundamental issue of the ease of the conditionability of the hysteric has, with very few exceptions, been ignored in favour of conjecture and supposition based on so called clinical experience. Some valuable experimentally derived data are, however, available.

Tinel and Michon (1928), in an intensive study of one case of hysteria, were able to demonstrate the role of the conditioned reflex based upon the occurrence of an initial trauma, (the evidence in favour of one trial learning will be presented at a later stage in this chapter). (The experimental induction of a "conversion symptom" has been demonstrated by Liddell (1944) who, by the application of conditioning techniques, induced a limb rigidity in a sheep which persisted for several years after the animal was removed from the original situation.) McGill and Welch (1947)¹ and Kennedy (1940) have produced a conditioned response theory of hysteria and its treatment; both projects unfortunately omitted first to investigate the basic conditionability of their hysteric groups. In view of data to be presented shortly to the effect that hysterics condition poorly, this makes the advocacy of reconditioning therapy of limited value unless combined with the use of various drugs and other procedures which have been shown to modify the ability to form, retain and extinguish conditioned responses.

Although it is probably more difficult to establish conditioned responses in hysterics, there are many examples that such a procedure can become effective

¹ Welch, at least, is aware that the conditioning process in hysterics may well be "difficult and exceptional" and, in two of his publications (Welch and Kubis 1947*a*, 1947*b*), provides incidental comments to this effect.

under certain conditions. Sears and Cohen (1933) were able to establish a conditioned response in a case of hysterical anaesthesia, but *only* by utilizing the principle of irradiation from one sense modality to another; it could not be established by simple reinforcement or by irradiation within the same sense modality from one part of the body to another. Cohen and his colleagues (Cohen, Hilgard and Wendt, 1933) also succeeded in conditioning an hysterically "blind" eye to respond to a light stimuli. Warren and Grant (1955) found that conditioned eyeblink discrimination was less in a group of subjects scoring high on the psychopathic deviate (Pd) scale of the M.M.P.I. than in those subjects with low Pd scores. Lykken (1957), in a study to be considered in some detail at a later stage, made an important contribution to the meagre knowledge concerning the conditionability of various kinds of psychopaths. His otherwise excellent study is marred by a failure to compare his psychopaths and normals with a group of dysthymics.

Since little attention has been given to the conditionability of specific neurotic subgroups, it is inevitable that even less attention has been given to a *comparison* of the conditionability of various subgroups. Darrow and Heath (1932) report that their extraverts, as measured by a personality questionnaire, tend to form conditioned P.G.R. responses slightly more readily than their introverts. However, these findings are of almost no value since the questionnaire used is, at best, of doubtful validity. Their introversion-extraversion scale was that of Gilliland and Morgan (1931), for which the standardization group of "extraverts" consisted of manic-depressives!

Ericksen (1954), in two rather complex avoidance and non-avoidance conditioning experiments, found that a hysteric group of subjects showed significantly more stimulus generalization than a psychasthenic group, using the respective M.M.P.I. scores as criteria in all cases. Taylor and Spence (1954) compared the conditionability of anxious neurotics with "other neurotics" and failed to find any statistically significant differences. The group of "other neurotics" included alcoholics, general depressives, obsessives, compulsives and psychopaths. To account for the failure to differentiate these two groups by means of conditioning, it is necessary first to consider in some detail a theory which provides an alternative explanation of (why anxiety is positively related to ease of conditioning)

Present Theory

(Pavlov's theory of cortical functioning emphasizes two basic cortical processes, *excitation* and *inhibition*). It is impossible to define these terms without embark-

ing upon considerable and highly dubious speculation of a neurophysiological nature, and it is sufficient here to regard them as hypothetical molar constructs, both of which are positive in nature. Inhibition, it should be noted, is *not* regarded as merely the absence of excitation. (Considerable confusion is brought about, both in the works of Pavlov and other authors, by the unfortunate multiplicity of usages of the term "inhibition," which is widely used in at least three different senses. There is the general psychiatric usage to describe the behaviour of the introverted, withdrawn individual; there is the more precise, but not clearly understood, neurophysiological use; and there is the Pavlovian usage to describe a hypothetical positive molar cortical process. It should be stressed that cortical inhibition in the Pavlovian sense, which is, fundamentally, how the term is used here, should be associated with the *absence* of behavioural inhibition in the psychiatric sense.)

Following a plethora of experiments on the conditionability of dogs and the induction of experimental "neuroses" in animals, Pavlov likened the kinds of neuroses developed in his various types of dogs to those found in man. He made many speculations about the causes of various human mental disorders in terms of pathological variations in his two cortical processes, but, which is not surprising, in view of the many incompatible and certainly confusing statements concerning the central concomitants of neurotic abnormality, never followed up any of these observations. One such observation (Pavlov, 1927, p. 397 *et seq.*) was to the effect that neurasthenics possess an exaggeration of the central excitatory process, whereas hysterics possess an exaggeration of the central inhibitory process. Quite different statements have been made by Pavlov elsewhere in his works and this observation is of value chiefly as a starting point for the theory of conditioning and personality about to be presented here.

It is possible to deduce from Pavlov's statement that neurasthenics would form positive conditioned reflexes readily, and that, once formed, these reflexes would be slow to extinguish, whereas hysterics would form positive conditioned responses only with difficulty and that these responses would be extinguished fairly readily. However, the term *neurasthenia* is ill defined and rarely used in contemporary psychology, and it would seem germane first, to examine both *neurasthenia* and *hysteria* more carefully in an attempt to discover how they differ, and then, to utilize equivalent terms more in accord with contemporary nomenclature.

Neurasthenia and hysteria are generally regarded as two differing forms of neurosis, and consequently, if a dimensional personality framework be accepted, they must differ along some dimension other than

neuroticism. Pavlov himself has implicitly suggested a possible dimension, namely the excitation-inhibition ratio, the neurasthenic being at the excitation-dominated end of the continuum and the hysteric at the inhibition-dominated end. As already indicated, such a dimension, being located centrally, is highly speculative, and its existence has to be inferred largely from peripheral observations made at the behavioural level. It is, therefore, necessary to seek a corresponding dimension of personality which may be described more directly and to which Pavlov's more hypothetical concepts may be related. In seeking such a dimension at the behavioural level the concepts of Jung seem most apposite. Jung (1924) has suggested that the characteristic neurosis of the extravert is hysteria whereas that of the introvert is psychasthenia; he also stressed the essential independence of introversion from neuroticism.

These ideas have been extended and systematized by Eysenck and his colleagues (1953) and, by the application of factor analysis, two orthogonal dimensions of personality have been isolated, namely, extraversion-introversion and neuroticism. (The existence of other orthogonal dimensions need not be of concern in the present discussion.) It has been shown that it is possible to describe neurotics classified in various ways in terms of their factor loadings on these two dimensions. Anxiety neurotics, obsessive-compulsives and reactive depressives, (collectively termed *dysthymics*) tend to have high scores on tests of neuroticism together with high scores on tests of introversion, but low scores on tests of extraversion, whereas hysterics and psychopaths have high scores on tests of neuroticism, but low scores on tests of introversion and high scores on tests of extraversion. These different kinds of neurotics differ essentially not along the dimension of neuroticism but along the dimension of introversion-extraversion.

Now the term "neurasthenic" is not a very definite entity and, from Pavlov's usage, would seem to embrace mild depressives, various fatigue states and some anxiety conditions; thus it seems reasonable to identify the concept of neurasthenia, associated with an exaggeration of the central excitation process, with Eysenck's concept of dysthymia. Similarly, it would seem reasonable to identify Pavlov's concept of hysteria, associated with an exaggeration of the inhibition process, with Eysenck's concepts of hysteria and psychopathy.

The behaviour of patients usually included in these categories lends strong support to the assumption that dysthymia is related to excessive *excitation*, and hysteria and psychopathy to excessive *inhibition*. Thus the dysthymic tends to present the following types of symptom; anxiety, compulsive thoughts and actions, oversensitivity to his environment, over-caution,

hesitancy, hyperactivity; he may be over-conscientious, irritable, introspective, ill at ease and agitated. All these characteristics are consistent with a presumed state of exaggeration of the central excitation process. Conversely the hysteric tends to be lacking in the above qualities; he is more likely to be impulsive, irresponsible and unreliable, to be insensitive to his environment and to the feelings of other people, and his responsiveness to his environment tends to be superficial and indiscriminatory. His abnormalities are more likely to be of a dissociative character such as fugues, escape mechanisms and other conversion symptoms. These characteristics would seem highly consistent with a presumed state of predominating cortical inhibition.

According to Eysenck's factorial studies, both the psychopath and the hysteric are extraverted and neurotic. By psychopath is meant the individual who has a history of asocial acts and who lacks the ability to control his immediate emotional responses. Superficially charming, he is nevertheless erratic and purposeless in his way of life and not truly responsive either to his general environment or to the feelings of other people. He is egocentric and lacking in moral qualities or a value system. Above all, he is highly unlikely to profit from past experience or to respond favourably to psychotherapy, love, discipline or intensive training. The striking similarity between the psychopath and the hysteric is discussed at length elsewhere (Franks, 1956a) and there would seem to be ample justification for regarding the psychopath, like the hysteric, as possessing an exaggeration of the central inhibitory process.

It seems, therefore, that both behaviourally and symptomatically neurotics differ from each other along the dimension of introversion-extraversion, and that the underlying central concomitant, presumably constitutional, may be found in the changing balance of the excitation-inhibition ratio, ranging from a predominance of excitation at the introverted (dysthymic) end to a predominance of inhibition at the extraverted (hysteric-psychopathic) end. If this is so, then an excitation-inhibition postulate should be tenable in accounting for many of the behavioural differences observed in normal introverts and extraverts.¹ It is the normal introvert who tends to possess the excitatory phenomena of hesitancy, conscientiousness, sensitivity and responsiveness to his environment; it is the normal extravert who tends to possess

¹ A neglected, but similar, theory is that originally propounded by McDougall to account for the differences obtained between introverts and extraverts in terms of a chemical theory of personality. McDougall (1929) postulated a mysterious substance which acts upon the nervous system so as to counteract the controlling activities of the cortex upon the more primitive lower levels of the brain. According to McDougall the extravert is the individual who is constitutionally provided with a large amount of this antidotal substance.

the inhibitory phenomena of impulsiveness, a lesser degree of conscientiousness and a certain lack of sensitivity to his environment.

The general hypothesis may now be stated that conditionability is related not to the degree of neuroticism present, but centrally to the postulated excitation-inhibition balance and behaviourally to the introversion-extraversion balance of the individual

and Withers, 1955). Using both eyeblink and P.G.R. reflexes it was found that anxiety states and other dysthymics (all introverted) conditioned significantly more easily than a group of hysterics and psychopaths (all extraverted) (Franks, 1956b). A group of normal subjects, being as a group neither extraverted nor introverted, tended to occupy an intermediate position (see Fig. 12.1). Furthermore, when the conditioning

FIG. 12.1. THE TOTAL NUMBER OF CONDITIONED EYEBLINK RESPONSES GIVEN BY TWENTY DYSTHYMICS (D), TWENTY NORMALS (N), AND TWENTY HYSTERICS AND PSYCHOPATHS (H) AT EACH TEST TRIAL

Note. The data reported in this and all other figures in this chapter, with the exception of Fig. 12.7, are obtained from a partial reinforcement conditioning schedule in which eighteen test or acquisition trials are interspersed irregularly among thirty reinforced trials, this is then followed immediately by a series of ten successive extinction trials.

concerned (Eysenck, 1957). An introverted subject, be he neurotic or normal, should form conditioned responses readily and these responses, once formed, should be difficult to extinguish; an extraverted subject, be he neurotic or normal, should form conditioned responses poorly and these responses, once formed, should extinguish readily.

Now, on both Spence's drive theory and on the above theory, anxious subjects would be expected to generate conditioned responses readily, hence a study confined to anxiety states would not provide a crucial experiment. A crucial experiment would have to examine both anxious and hysteric neurotics. On Spence's theory, since neuroticism is a drive, both groups should condition readily; on the present theory only the anxiety group should do so.

This crucial experiment was carried out in a sound-proof conditioning laboratory especially designed for this purpose (Franks, 1954; Franks 1955; Franks

data were correlated with various personality questionnaires (see Franks, 1956b) the predicted relationship was found with introversion-extraversion (a high extraversion score indicating poor conditioning) and a marked lack of relationship with neuroticism.¹

¹ The chimerical objection of Jenkins and Lykken (1957) that the three groups were not equal in the strength of the conditioned response on the very first trial, i.e. before any conditioning could have taken place, is unwarranted since only subjects who *failed* to give an original response to the conditioned stimulus were included in the experiment. In other words *all* subjects were equal in their strength of conditioning prior to any reinforcement being given. The fact that in some of the data reported the slopes of the curves are probably not significantly different for different groups suggests that, if confirmed, certain aspects of the theory, as presented, require substantial modification. It does not vitiate the general conclusions regarding the differential conditionability of introverts and extraverts. The suggestion of Jensen (1958) that differences in spontaneous eyeblink rate may account for the differences in eyeblink "conditionability" is plausible but inadequate to account for the obtained differences (see Franks, 1954). A similar and equally untenable argument is presented by Meyer (1953); based on the fact that induced general

These conclusions, especially those concerning the conditionability of dysthymics in general compared with hysterics in general, are limited by the method of selection of the patients included in the above experiment. The two neurotic groups were deliberately chosen to minimize overlap on the dimension of introversion-extraversion by selecting only those subjects who produced extreme scores on a questionnaire measure of extraversion. Hence the sample of

obtained (*see* Figs. 12.2 and 12.3). The only study to refute these findings is a dissertation of Das (1958), who failed to find significant correlation between conditioning and introversion-extraversion. (The correlation with extraversion is in the predicted direction.) On the other hand, Shagass and Kerenyi (1958), in Canada, obtained a highly significant correlation between ease of eyelid conditioning and introversion, using Guilford's questionnaires and a

FIG. 12.2. THE TOTAL NUMBER OF CONDITIONED EYEBLINK RESPONSES GIVEN BY THE FIFTEEN MOST EXTRAVERTED SUBJECTS (BROKEN LINE) AND BY THE FIFTEEN LEAST EXTRAVERTED SUBJECTS (SOLID LINE)

These two extreme groups, as regards introversion-extraversion, were selected from a random sample of fifty-five male students who were all conditioned and given a personality questionnaire by two experimenters working independently.

FIG. 12.3. THE TOTAL NUMBER OF CONDITIONED EYEBLINK RESPONSES GIVEN BY THE FIFTEEN MOST NEUROTIC SUBJECTS (BROKEN LINE) AND BY THE FIFTEEN LEAST NEUROTIC SUBJECTS (SOLID LINE)

These two extreme groups, as regards neuroticism, were selected from the same fifty-five subjects used to provide the data illustrated in Fig. 12.2.

patients finally accepted for conditionability cannot be considered as typical. That this limitation is not serious is apparent from the fact that only eight out of twenty-eight hysterics were initially rejected as not being sufficiently extraverted and seven out of twenty-seven dysthymics because of a corresponding lack of introversion. In any case, when a similar (Franks, 1957b) experiment was carried out with a much larger sample of normal subjects, similar results were

muscle tension increases spontaneous blink rate and the assumption that a high score on the Taylor scale represents an "unusual amount of muscular activity," he argues that the superior conditionability of anxious subjects can be accounted for in terms of a greater "facilitation" of the eyeblink reflex. That the argument is untenable is apparent from an examination of the spontaneous blink rate of various neurotics and from the succinct observations of Bindra and his colleagues (1953). Jensen has also criticized the main conclusions on the ground that the relationship between introversion-extraversion and conditioning was obtained from one measure only, namely the eyeblink reflex. Apart from the fact that, as reported, similar results have been obtained for the conditioned P.G.R. response (Franks 1956b), Eysenck (1960) has recently presented evidence suggesting a reasonable degree of concomitance between a number of different conditioning measures and introversion-extraversion.

technique similar to that of Das and the present author.

In general then, the above experiments confirm the introversion-extraversion theory of conditioning and fail to support Spence's drive theory. They also make it possible to account for the fact that most previous studies which examined the conditionability of groups of neurotics found them superior to normals despite the fact that conditionability should be unrelated to neuroticism if the theory now being discussed is correct. The explanation is a practical one, rather than theoretical; among any unselected group of hospitalized neurotic patients the dysthymic variety are likely to preponderate; the psychopaths and hysterics are more likely to go to prisons or night clubs, or refuse to accept voluntary admission into a psychiatric hospital. In the one group where information about the neurotic sample is provided (Taylor and Spence, 1954) it will be recalled that no differences were found in conditionability between anxiety states on the one hand and a mixed selection of alcoholics, depressives, obsessives, compulsives and psychopaths,

etc. on the other hand. Since both groups contained large numbers of introverted neurotics (dysthymics) it is hardly surprising that no differences in conditionability were obtained!

It will be noticed that the introverted group in particular tend to achieve fairly well-established conditioning after as few as two reinforcements. This, of course, is no unusual phenomenon in conditioning experiments and cases of only one trial learning have

presents the results of a typical study (Franks and Trouton, 1958) in which normal subjects were allocated at random into one of three major groups, those receiving dextrodine, those receiving a *placebo* and those receiving Sodium Amytal. All three groups differed significantly from each other, the stimulant or excitatory drug increased conditionability and the depressant drug decreased. In earlier studies (Franks and Laverty, 1955; Laverty and Franks,

FIG. 12.4. MEAN NUMBER OF CONDITIONED EYEBLINK RESPONSES GIVEN BY GROUPS OF NORMAL FEMALE SUBJECTS RECEIVING DEXEDRINE, PLACEBO, OR SODIUM AMYTAL

Two experimenters were involved; one was responsible for giving the drugs or *placebo* and for other administrative arrangements, the other had no other contact with the subjects apart from operating the conditioning equipment.

not only been reported (e.g. Hudson, 1950) but have been given theoretical approval (Guthrie, 1952). The data provided by Kimble (Kimble, Mann and Dufort, 1955; Kimble and Dufort, 1956), as part of a series of experiments on the associative factor in eyelid conditioning, confirm the readiness with which eyelid conditioning takes place. He concludes that "the associative process in eyelid conditioning develops much more rapidly than the usual learning curve would lead one to believe."

In another series of experiments (Bartholomew, Franks and Marley, 1958; Franks and Laverty, 1955; Franks and Trouton, 1958; Franks, Trouton and Laverty, 1958; Laverty and Franks, 1956) drugs were used to produce central stimulant or depressive effects. (Eysenck (1957) has proposed a theory relating the effects of *stimulant* drugs to increases in introversion, and the effects of *depressant* drugs to increases in extraversion, cf. also Chapter 17 of this HANDBOOK, by Trouton and Eysenck.) Fig. 12.4

1956) it was found that a depressant drug reduced conditioning as predicted and, at the same time, increased the subjects' extraversion scores, while not altering their neuroticism measures.

The value of these findings is limited by a serious difficulty of interpretation. It is reasonable to believe that stimulant and depressant drugs have peripheral actions as well as central ones. Settlage (1936) gave cats a dose of amytal which was sufficient to prevent the performance of any conditioned response, while leaving the original unconditioned response unimpaired; after recovery from the drug, subsequent testing without any further reinforcement showed that a conditioned response had been successfully formed even though it never appeared during training and testing while the animals were under the influence of the drug. In the drug experiments cited above it is impossible to determine to what extent the findings reflect the peripheral motor consequences of the drugs concerned and to what extent they reflect any direct

effects upon a central learning or connexion formation process. For example, the data illustrated in Fig. 12.4 would have been of much greater value had some additional testing of the degree of conditioning been carried out *after* the subjects had completely recovered from the effects of the drug. (For administrative reasons, this was impossible; however, an experimental investigation of this problem is almost complete at the time of writing.)

Despite this limitation it is instructive to compare the "conditioning curves" of normal subjects under the influence of drugs with the corresponding curves obtained from undrugged subjects belonging to various extreme groups. The similarity between the conditioned response behaviour of normal introverts, neurotic introverts (dysthymics) and subjects who have received a stimulant drug is very evident from the diagrams presented in this chapter. An equally striking parallel exists between the conditioned response behaviour of normal extraverts, neurotic extraverts (hysteries and psychopaths) and subjects who have received a depressant drug. The fact that it is possible to simulate certain aspects of neurotic behaviour by the application of centrally-acting drugs is of considerable theoretical and practical significance.

There is evidence in the literature (reviewed in Franks, 1956a; Franks and Trouton, 1958) to suggest that certain brain-damaged subjects (due either to natural or operative causes) tend to form conditioned responses only with difficulty, and that, in general, depressant drugs have a similar effect, whereas stimulants have the opposite effect upon conditioning. It is also remarkable how the theoretically predictable increase in extraversion tends to occur as a result of depressant drugs such as alcohol (Franks, 1958a) or of natural brain damage, or following certain forms of psychosurgery (Franks, 1956a). As Mayer-Gross, Slater and Roth (1954) point out, hysteric and psychopathic reactions are not uncommon following prefrontal leucotomy, and it is following certain physical illnesses, especially those involving the cortex, such as encephalitis lethargica, that hysteric and psychopathic symptoms sometimes occur. Kennedy (1954) also stresses the similarity between certain hysterics, brain-damaged subjects and psychopaths and postulates a constitutional similarity between these groups (cf. Chapter 15 of this HANDBOOK by R. Willett, for an extended discussion of the relation between brain damage and personality, cf. also Eysenck, 1957, for a general theory of personality change after brain damage).

It is now possible to account for the fact that, despite theoretical reasons why anxious subjects should condition more readily than non-anxious, many of those studies which made use of the Taylor scale as their measure of anxiety produced only slight

and sometimes insignificant confirmation of this relationship. The explanation seems to be that the Taylor scale is largely a measure of neuroticism (it correlates 0.92 with the Maudsley Medical Questionnaire and 0.86 with Guilford's D and C scales, which are all good measures of neuroticism) and only to a slight extent with measures of extraversion (Franks, 1954). Considerable experimental evidence from numerous studies by different authors is presented elsewhere (Franks, 1956c; Franks, Souief and Maxwell, 1959) to confirm that Taylor's Scale has a very considerable projection on to the neuroticism dimension and a relatively slight projection on to the introversion end of the introversion-extraversion dimension. This slight projection may account for the usually positive, always low and occasionally insignificant results obtained by Spence and his colleagues, and the fact that to get good results extreme groups have to be taken.

The failure of Bindra *et al.* (1955) to find any relationship between rate of salivary conditioning and scores on Taylor's Scale is hardly surprising. It should be pointed out that Bindra is a drive theorist and believes that his study gives support to an hypothesis originally proposed by Hilgard, Jones and Kaplan (1951). These authors state that anxious subjects, being more apprehensive, regard the air puff as a threatening stimulus. Therefore, since the eyeblink response is a protective one, anxious subjects are more likely to make the conditioned avoidance response than are non-anxious subjects. It must be noted that both Spence and Hilgard attribute differences in eyelid conditioning to differences in drive, but whereas Spence conceives of anxiety as part of a general heightened drive level, Hilgard appears to think in terms of a specific defence or protective drive. It is a pity that all of these authors used a measure only of neuroticism (the Taylor "anxiety" scale) and none of introversion-extraversion. The distinction between considering *relevant specific drives* and *drive in general*, including irrelevant drives, is a fundamental one and will be referred to again. (It is of interest to note that scores obtained from Taylor's scale do not even agree with psychiatric rating of "anxiety"; for example, both Bitterman and Holtzman (1952) and Franks (1954) failed to obtain significant correlations between ratings of anxiety obtained from Taylor's scale and ratings independently obtained by clinical assessments.)

Further evidence concerning the nature of Taylor's scale in relation to conditionability is to be found in a recent study by Lykken (1957). He found that psychopaths with a high score on Taylor's scale did not condition more readily than a group of subjects with significantly lower scores on her scale. If Taylor's scale is primarily a measure of neuroticism this result

is in accord with the theory of conditioning presented in this chapter. Unfortunately, Lykken used no direct measure of extraversion: however, he did administer the Pd (psychopathy) scale of the M.M.P.I., which has been shown (Franks, Souief and Maxwell, 1959) to be to some extent a measure of extraversion, and he found that subjects who scored high on this scale tended to condition poorly *irrespective* of their position on the Taylor scale. Thus independent doubt is cast both on the nature of the Taylor scale and on the concept of drive as a conditioning variable under *all* circumstances.

The experiments cited, and arguments developed, all indicate that Taylor's anxiety scale is largely a measure of neuroticism and that individual differences in conditionability seem better accounted for in terms of introversion-extraversion than in terms of the Spence-Taylor theory of neuroticism or anxiety as a drive.¹ But before proceeding to a discussion of the clinical and practical implications of the introversion-extraversion theory of conditioning, it is appropriate to consider briefly some further reasons why the drive theory of Spence and Taylor is believed to be partly erroneous.

As already indicated, their theory is based upon the assumption, taken from Hull's postulate system, that the total effective drive level is determined by the summation of all existent needs, both primary and secondary, and irrespective of their source and relevance to the nature of the reinforcement. If this is correct, then it should apply to variations in drives other than anxiety. It should hold for drives such as hunger and thirst. Experimentally these drives offer distinct advantages over that of anxiety, which is difficult to manipulate except in the indirect and crude method of group selection by means of a questionnaire or rating scale which is believed to be an adequate and valid measure of anxiety. It might be expected that the Taylor scale would at least be capable of yielding a meaningful quantitative score from which the amount of anxiety could be inferred; on the contrary, there is good evidence to believe that different scores on the Taylor scale do not represent different amounts of anxiety. (Sampson and Bindra, 1954.) The appetitive drives can be manipulated directly and with a far greater degree of certainty than the required modification is being effected. If the Spence-Taylor paradigm is correct then one would

expect an increase in hunger and thirst to produce an increase in the ease of conditionability *whatever reflex is being measured*.

To test this prediction sixty normal male undergraduates were allocated at random to one of two groups, a "high drive" group who were rigorously deprived of any food, drink and tobacco throughout the day and a "low drive" group who were allowed to eat, drink and smoke in the usual manner (both groups contained approximately equal proportions of smokers.) At the end of the day all subjects were conditioned, using the frequency of conditioned eyeblink responses to a tone stimulus as the measure of conditioning (Franks, 1957a). The results, presented graphically in Fig. 12.5, indicate clearly that increasing *D* by food, drink and tobacco deprivation fails to produce any increase in the ease with which the eyelid response can be conditioned to a sound stimulus. Consequently the present study, like that of Buchwald and Yamaguchi (1955), who investigated the effects of water deprivation upon habit reversal in the rat, fails to give any support to the drive theory of conditioning as used by Spence. It is important to realize at this point that the above experiment only refutes the postulate that drive is relevant to conditionability *irrespective* of the reinforcement and nature of the reflex used. Thus Bindra *et al.* (1955) failed to find any relationship between scores on Taylor's anxiety (or neuroticism) scale and the rate of salivary conditioning. But when the drive is a relevant one, such as hunger in a learning situation directly involving food, there is no doubt that it is also relevant to the efficiency of learning or conditioning. Although hunger does not modify the learning of the conditioned eyeblink response, it certainly increases the ease and rate of conditioned salivation¹. This has been demonstrated on both animals (Zener and McCurdy, 1939) and humans (Lashley, 1916; Winsor, 1928).

Even in those cases where the drive is relevant to the learning situation, the response strength is not as Spence would have his readers believe, a linear positive function of the intensity of the drive. Birch (1945) manipulated the relevant drive of food deprivation to investigate the effects of motivation in various problem-solving tasks in chimpanzees. Using six different degrees of deprivation ranging from two to forty-eight hours, he found that problem-solving

¹ Because Kamin (1955) found that his subjects' scores on a mechanical aptitude test were related to their learning he concluded that the superior conditioning of anxious subjects on tests of eyelid conditioning was a negative function of their familiarity with mechanical and electrical apparatus. Although it is premature to assume a causal relationship between the two measures on no further evidence than a correlation coefficient, this raises interesting possibilities concerning attitudinal and situational factors which may also modify conditionability.

¹ Hilgard, Jones and Kaplan (1951) argue that eyelid conditioning may be conceived of as an instrumental avoidance situation in which anxious subjects feel greater need to blink and thus avoid the noxious stimulus. In this case anxiety is a relevant drive to instrumental eyelid conditioning. However, in the series of eyeblink reflex experiments described in this chapter this seems to be an unlikely description of what happens; in the first place the air puff is scarcely noxious, a very mild stimulus being quite sufficient to produce a reflex blink; in the second place, the blink latency and duration are such that the air puff is not avoided.

efficiency was greatest under intermediate conditions of hunger. In short, Spence's use of Hull's postulate is too general and leads to erroneous deductions. A better formulation is that irrelevant drive is irrelevant to conditioning, the relevant variable being the postulated excitation-inhibition at the central level or introversion-extraversion at the behavioural level. When the drive is relevant to the conditioning or

certain circumstances, anxiety actually interfered with learning. As a consequence of this and other studies, Furber and Spence (1953) revised their theory and developed a rationale to predict that anxious subjects should perform more poorly than non-anxious subjects in situations involving competing responses. A recent carefully planned study by Saltz and Hoehn (1957) failed to confirm even this revised theory of

FIG. 12.5. MEAN NUMBER OF CONDITIONED EYEBLINK RESPONSES GIVEN BY "HIGH DRIVE" AND "NORMAL DRIVE" GROUPS OF NORMAL MALE SUBJECTS

learning situation then the strength of the response is relevant to the strength of the drive, with the proviso that the probable relationship is a curvilinear one rather than a positive linear function (cf. Chapter 19 by P. Broadhurst).

It is of interest to note that Spence's theory of manifest anxiety as a drive variable has been shown to be inadequate in other areas. Thus Montague (1953) found little evidence that anxiety facilitates verbal learning and strong indications that, under

anxiety as a drive in learning. Probably the clearest and most useful statement of the influence of relevant drives on learning and performance is given in the Yerkes-Dodson law: the more complex the task the lower the optimal drive level; the simpler the task the higher the optimal drive level. A discussion of this principle is beyond the scope of the present chapter and for an extended treatment the reader is referred elsewhere. (Eysenck, 1957; Young, 1936; also Chapter 19 of this book.)

CONDITIONING AND PERSONALITY: APPLICATION OF THE THEORY

The behaviour patterns of the dysthymic and of the hysteric have so far been considered largely in terms of an excess of the hypothetical processes of excitation and inhibition. If it be accepted that the dysthymic neurotic conditions readily and the hysteric poorly, it should be possible to proceed from the level of hypothetical constructs in the sense implied by McCorquodale and Meehl (1948) to a partly speculative, but certainly more direct, description of symptomatology and behaviour in terms of conditioning.

Through excessively strong and persisting conditioned response mechanisms, fear reactions in the dysthymic become conditioned response patterns to stimuli which are innocuous and neutral for other individuals. Thus the excessive anxiety which is so characteristic of dysthymia becomes a generalized and persistent response pattern. In a similar way the phobias, obsessions, compulsions and ruminations, etc. may be accounted for by taking into account the significant advances in the understanding of the

methods by which verbal conditioning may be achieved. The fact that in many of these experiments the subject is *unaware* of the conditioned stimulus and of the fact that he is being conditioned is of importance. In certain circumstances particular situations have been shown to act as conditioned cues, highly specific to the patient and often without his awareness. There would seem to be no need to invoke psychoanalytic concepts to account for these phenomena.

In certain instances the individual receives only one traumatic reinforcement and it might be wondered whether this is sufficient, even in the most rapid of conditioners, to establish a persistent conditioned response. From laboratory experience many instances can be recalled of strong conditioning being established in very introverted neurotics after as few as two reinforcements. As already stated, experimental confirmation of single-trial conditioning has also been provided by Hudson (1953), and Guthrie (1952) has given a possible theoretical explanation of how such a situation might come about.

The hysterico-psychopath group has been described behaviourally in terms of some form of central inhibition or dissociation. If it is confirmed that such individuals form conditioned responses only with difficulty, and that these responses are readily relinquished, then it becomes possible to describe these individuals in terms of a difficulty in forming and ease in losing conditioned responses.

It is hardly necessary to labour the point by considering the behaviour patterns of the normal introvert and extravert in relation to their ability to form conditioned responses. The introverted normal and the dysthymic have similar behavioural characteristics, but the normal lacks the high neurotic (emotional) drive of the dysthymic; the extraverted normal resembles the hysteric but does not have his neurotic (emotional) drive.

It occasionally happens that a subject's questionnaire score of introversion-extraversion is diametrically opposed to his ease of conditioning as predicted in accordance with the theory of personality outlined above. Disregarding, for the moment, problems of errors in procedure or in matters of test reliability and validity, this apparent inconsistency can still be accounted for without vitiating the theory. Consider for example the person who conditions readily and yet gives a high extraversion score on questionnaires measuring his social behaviour pattern. It is at least possible that such an individual is an introvert and conditions readily, but is living in a cultural pattern where extraverted behaviour is the socially desirable and acceptable norm. Such a person would learn the pattern readily and consequently respond as an "extravert" on the questionnaires. If this hypothesis

is correct he should behave as an introvert on all measures of central excitation, such as sedation threshold, flicker fusion, Archimedes spiral, which are unaffected by social demands, and as an "extravert" on tests such as questionnaires or verbal interviews. It also follows, since the introvert on physiological tests can learn the extraverted pattern of social behaviour fairly easily if needs be, whereas the extravert on physiological tests can learn an introverted pattern of social behaviour only with much difficulty, that inconsistencies between conditioning and questionnaires should be greater for good conditioners than for poor. This is a testable prediction which may give rise to interesting research.

Delinquency

One of the most challenging and widespread problems in modern society is that of the *modus operandi* of the delinquent personality. At first impression it might seem feasible to subsume delinquency under the more general heading of psychopathy, (but this would imply that all delinquents are extraverted, which is a simplification unwarranted by the facts. However, at least two studies (Gluecks, 1950; Miller, 1956) have shown that, although both introverts and extraverts can, and do, become delinquents, it is the extraverted children who tend to become the habitual juvenile and adult delinquents. It may be that behaviour which is commonly classified as psychopathic can be further resolved into two broad subgroups, a group of asocial offenders who just do not conform to society and another group of antisocial offenders who are against society (Franks and Willett, 1956).

This hypothesis is based on the finding that certain psychopaths find great difficulty in forming conditioned responses and that, once formed, these responses are soon extinguished. These psychopaths are also extraverted in personality. It is characteristic of such individuals that they are unable to learn from experience or punishment or to profit from help offered them, whatsoever its nature. Such individuals are those who become the "true" psychopaths; they are asocial in as much as they are unable to learn the rules of society. There may be, however, another group of delinquents who are very capable of conditioning and learning the rules of society. Unfortunately, the rules they acquired from their microcosmic section of the environment in which they exist are regarded as undesirable and antisocial by the vast majority of mankind. From their neighbourhood, family, friends and mass media such as the cinema they readily acquire a conditioned pattern of delinquent behaviour. If the theory of conditioning outlined here is correct, then such individuals would tend to be relatively introverted.

The concept of recidivism now takes on new attributes and a new complexity. In the search for the causes which contribute to recidivism many possible factors have been examined. For example, attempts have been made to relate the dimension of intelligence to the incidence and nature of recidivism, but, so far, no consistent relationships have emerged. (Franks, 1956a). When recidivism is examined in terms of the dimension of conditionability, i.e. of introversion-extraversion, two interesting possibilities arise. Some recidivists would have learned antisocial behaviour patterns from the undesirable environment in which they live. Even their repeated prison sentences, if largely custodial, would merely provide a reinforcement of the undesirable society whose patterns they learned so well. These recidivists, if the present theory is correct, could be detected by their tendency towards introversion and by their ease of conditionability in laboratory tests. They are the non-psychopathic recidivists who, if they are highly responsive to undesirable training, should be equally responsive to more desirable treatment in the form of psychotherapy and re-education, etc.

At the same time there might exist another group of recidivists, extraverted in personality and very poor at forming conditioned responses. These recidivists should be classified as truly psychopathic, i.e. asocial, rather than antisocial. They would not respond to any form of training or treatment and would be constitutionally largely unable to acquire the rules of the society in which they lived. In an era where an acute shortage of psychotherapists and facilities for skilled remedial training predominates a selection device based on personality and conditioning tests would be invaluable. An interesting, and readily testable, corollary is that the introverted delinquents should have come from emotionally or materially undesirable environments whereas the extraverted (psychopathic) delinquents, being indifferent to social learning, could have come from any sort of environment. None of the studies which have examined delinquents have related introversion-extraversion to home background in this way.¹

Although this theory rests on slender evidence and must be regarded as speculative, there is some independent confirmatory evidence which lends support to these conjectures. Lykken (1957), using the P.G.R. as his measure of conditioning, also found that his psychopaths were more difficult to condition than his normal group. His study is extremely provocative in that it raises many fecund possibilities

and is well worth considering here in some detail. Lykken makes explicit a differentiation which has long been implied in clinical practice; he differentiates between the neurotic psychopath (presumably an individual who has high scores on tests of extraversion and on tests of neuroticism) and the sociopath (presumably with high scores on tests of extraversion but only moderate scores on tests of neuroticism). Since both are extraverted, both should condition poorly and this is what Lykken found, despite the fact that he conceived his experiment in an entirely different framework to that propagated here.

Conditioning as a diagnostic tool could be used in settings other than penological. For example, in industry the problem of the accident-prone worker has received much attention. There is some evidence (Petrie 1949) to suggest that certain post-leucotomized patients become more accident-prone, as well as more extraverted, sometimes psychopathic and possibly poorer at forming conditioned responses. It is possible that the increased proneness towards accidents in such patients is explicable in terms of loss of those acquired responses which previously enabled them to guard against the many hazards of twentieth-century living. A related observation which could be interpreted in a similar manner (except that it would be a lack of formation, rather than a loss, of conditioned reflexes) is that of Eysenck (1947), who noticed that the characteristic of "accident proneness" is ascribed to themselves more by extraverts than by introverts.

The Effects of Drugs ✓

Psychopharmacology is becoming of growing importance, and every day new drugs, particularly stimulants and depressants, make their appearance. Now, if it is correct that stimulant drugs increase the ease with which new responses can be acquired and retained whereas depressants have the opposite effect, then psychotherapy (which may be reasonably regarded as an exercise in learning or conditioning) may profit from the judicious use of the correct drug at the correct stage in the proceedings. (For example, a stimulant drug might be used when building up the new response pattern and a depressant drug when extinguishing an old and undesired pattern of behaviour.) It is, however, an empirical fact that sufficient reliance cannot be placed on prediction of the effective dosage by utilizing such variables as lethal dose, age, sex or body weight. (It is possible that this major difficulty might be overcome by an application of the theory of personality and conditioning) presented in this chapter.

It has been postulated that introverts condition readily because of an effective exaggeration of the excitation process and that extraverts condition poorly because of an effective exaggeration of the inhibition

¹ From the point of view of the theory of personality and conditioning advanced in this chapter there is a considerable methodological advantage in working with such clearly recognized groups as delinquents and prostitutes, about whose behavioural "symptoms" there is no dispute (as contrasted with hysterics and dysthymics).

This rationale is applicable to the findings of psychologists working within quite different frameworks. For example, Sheldon and Stevens (1945) have observed that high resistance to alcohol is listed as one of the criteria for their cerebrotonic temperament. Since cerebrotonics seem similar to dysthymics this is to be expected. It also accounts for the subjective impression of McDougall (1929) who, in discussing the phenomena of alcoholic intoxication, said that: "In a number of cases the markedly extraverted personality is very susceptible to the influence of alcohol. A very small dose deprives him of self-restraint and control and brings on the symptoms of intoxication, all of which are essentially expressions of diminished cortical control over the lower brain levels. The introvert on the other hand, is much more resistant to alcohol. He can take a considerable dose without other effect than that he becomes extraverted."

McDougall provides no objective measures of introversion-extraversion and without such a measure it is impossible to predict accurately any individual's susceptibility to stimulant and depressant drugs. As already stated, the more or less empirical rules developed for the estimation of effective drug dosages are of only limited value and it is sometimes found that different individuals vary apparently inexplicably in their responses to the same drug (Goodman and Gilman, 1941). A possible reason for such individual differences in the susceptibility of subjects of the same weight and age, etc. may lie in their individual differences in the excitation-inhibition balance. Weight and age data provide necessary but not sufficient criteria; it may also be essential to have some objective assessment of the subject's excitation-inhibition balance before an accurate prediction could be made about his susceptibility to any specific stimulant or depressant. The experimental findings and theoretical formulation presented in this chapter provide such a way. The dosage required would be predicted from the subject's position on the introversion-extraversion continuum, which is the behavioural concomitant of his excitation-inhibition balance, from his conditionability, which is another measure of this balance, and perhaps from a measure of his sedation threshold. Although *much* further research is required, these methods may eventually be of value both for the prediction of the dosages

required to produce certain desired effects and for the rational investigation of the effects of new stimulants and depressants upon behaviour (cf. Chapter 17 of this HANDBOOK, by Trouton and Eysenck).

There are many complicating factors, not least of which is the fact that many drugs have side effects which may be of sufficient strength to obliterate the predicted effect. Thus many excitants are also sympathomimetics and many sedatives depress autonomic activity to a marked degree. From the research point of view it is therefore better to use stimulants and depressants (using these much confused terms in the pharmacological sense, as categorized by Goodman and Gilman, 1941) with the minimum of side effects, as far as this is possible. If tests of conditionability are used it is sometimes difficult to evaluate whether the central concomitants of conditioning are being modified or merely the peripheral performance of certain activities. Sometimes it is possible to overcome these side effects by the use of other agents, but it is then incumbent upon the experimenter to demonstrate that these other agents are innocuous as far as the main predicted effect is concerned.

For example, the tertiary amine arecoline (an alkaloid found in the betel nut) has a pronounced inhibitory effect on the performance of an already learned response, but unfortunately produces undesirable effects. Atropine, also a tertiary amine, would prevent these peripheral effects, but it cannot be used since it would also protect the brain from the desired effects of these drugs. However, if methyl atropine, a quaternary analogue, is used in combination with the arecoline, then the subjects would be protected peripherally from the undesired side effects, leaving the central effects to be observed unimpaired (Pfeiffer and Jenney, 1957).

To demonstrate this experimentally with humans, four groups of subjects were conditioned to a high degree of responsiveness, then group *A* was given the arecoline-methyl atropine mixture, group *B* methyl atropine alone, and groups *C* and *D* were used as control groups. The results show clearly that the arecoline mixture had a pronounced inhibitory response on the conditioned reflex under investigation and that this effect could not be attributable to the methyl atropine. These findings are indicated graphically in Fig. 12.7, in which, for the sake of clarity, the control data, being almost exact replicas of the methyl-atropine data, are omitted. The arecoline inhibits the performance of the learned response at first, then, as its effects gradually wear off, the response gradually appears again and is finally extinguished in the normal manner (Franks, Trouton and Laverty, 1958). Thus considerable care is essential in investigating the effects of new drugs, each of which

reason to believe that it is subject to limited fluctuation. Thus Slavina (1936) studied salivary conditioning in children throughout the waking day over a period of nine days and found consistent diurnal variations, conditionability being less in the first and last periods of each day. It is of theoretical significance that these diurnal variations in susceptibility to conditioning broadly follow the variations in other measures such as the electric sensitivity of the eye or the sensitivity of teeth to pain (Kleitman, 1939). There is, of course, no *a priori* reason why constitutional elements should not in themselves be subject to some form of inherent variation; manic-depressive psychosis is a classical example of such an oscillation.

may require a specific method of study; it is dangerous, for example, to assume that all tranquillizers have a depressant effect upon the formation and performance of a learned response.

Another complicating factor, more difficult to resolve because of the many speculations involved, is that of the apparently contradictory effects sometimes reported when working with certain drugs. It has more than once been reported that the effects of

FIG. 12.7. THE EFFECT OF ARECOLINE UPON THE EXTINCTION OF THE CONDITIONED EYEBLINK RESPONSE

amphetamine are sometimes paradoxical (e.g. Reifstein and Davidoff, 1939) and Carl and Turner (1939) repeatedly found, in their intensive studies of the psychological effects of amphetamine sulphate, that there was "a temporary period of lessened efficiency, actual retardation and perhaps even 'confusion' for a variable length of time after investigation, especially when the dosage is heavy." Recently, the present writer had occasion to suggest that a very introverted subject be given a fairly large dose of amphetamine sulphate by mouth. About half an hour later, much to everyone's surprise, the subject was fast asleep on a couch and it was not until much later that the more usual stimulant effects of the drug manifested themselves.

In order to account for these apparently paradoxical effects one must accept the theoretical relationship between drug action and personality developed here, together with a certain amount of speculation about the properties of the central processes involved and the effects of various drugs upon these processes. For example, it is logically possible to decrease any ratio

by increasing the denominator or by decreasing the numerator or by combining both operations. If the excitation-inhibition balance is regarded as a ratio this applies here also and considerable research is

FIG. 12.8. SOME TYPICAL EYEBLINK RECORDS

U.S. = the occurrence of the unconditioned stimulus (an air puff) together with the conditioned stimulus (a tone).
C.S. = the occurrence of the tone alone.

The top record is that of a subject who gives very little spontaneous blinking. (Also included in this record are the P.G.R. responses to the two sets of stimuli). The middle record is the kind most frequently encountered, namely that of a subject who gives some spontaneous blinking. The bottom record is that of a subject who gives a considerable amount of spontaneous blinking. It should be noted that in all these records it is very easy to distinguish the conditioned and unconditioned responses.

required into the subtle modes of action of the drugs concerned.

Pavlov considered, possibly on inadequate evidence, that caffeine produced its stimulant effect by "destroying inhibition." One might expect amphetamine sulphate, unknown at the time Pavlov was carrying out his experiments, to be an even greater "destroyer of inhibition," but logically, at any rate, its mode of action could equally well be by increasing the

excitation process. Whatever way the stimulant drug affects this ratio, the net result is a marked increase in the ratio in favour of excitation. So marked is this excitation, according to Pavlov, that a paradoxical phase of protective inhibition has to be established in order to preserve the cortical cells from damage. To discuss the possible mechanism by which this process is brought about would be both highly speculative and outside the scope of this volume. Perhaps the concepts of "induction" of Pavlov and Ischlondsky (1949) offer possible explanations. Whatever, the reason, there is some clinical evidence, e.g. the beneficial effects of sleep in times of stress and the effectiveness of various forms of sleep therapy (Korbbikov, 1955), to suggest that some such mechanism might possibly apply. In the case of the introverted subject, already in a state of excitation, the increased excitation provided by the stimulant drug was presumably sufficient to produce a state of excitation so excessive that it was necessary to adopt sleep as a form of protective inhibition.

This theory helps to account for the data obtained in a series of experiments in which it was desired to investigate the effects of a stimulant drug upon conditioning by comparing a group of drugged subjects with a *placebo* group. It was found that in order to obtain the predicted significant increase in conditionability it was necessary, with the intensity of dosage used, to allow two hours to elapse between the injection of the drug and the start of the experiment. When shorter intervals were maintained the drug failed to produce the predicted effects, even though the times were, pharmacologically, sufficient for absorption to have taken place. It would be interesting to investigate the production of paradoxical effects in a systematic manner by such means.

Throughout this chapter reference has been made to the use of drugs in the conditioning laboratory, both as experimental variables and as agents whose properties are to be investigated. Many of the inherent difficulties have been discussed already, but if the reader wishes to carry out such studies himself, or even to evaluate those studies which have been carried out by other workers, there are additional hazards of which he must be cognizant. Certain of these hazards are of particular importance because they indicate that the theory of drug action presented here is almost certainly a gross over-simplification.

Firstly the method of administration of the drug is of direct relevance to the effects produced, e.g. directly to the surface of the cortex, through intraventricular cannulae or systemically. Secondly, different doses of the same drug may produce differential effects which are not a linear or straightforward function of the size of the dose (Brown and Searle, 1938). Thirdly, the magnitude of the response depends, as one would

expect, upon the conditioning technique and reinforcement schedule utilized; it is important to realize this when comparing the results of different workers. Fourthly, in working with depressants, despite the evidence presented throughout this chapter, it is unwise to assume too close a similarity between the postulated inhibitory effects of drugs, natural brain damage, disease, psychosurgery, sleep, hypnotism and the postulated inhibition pertinent to certain personality types. For example, it has been shown that conditioning under anaesthesia does not follow the same pattern as conditioning in the decorticated animal; the use of depressant drugs in the study of conditioning cannot justifiably be regarded as merely a convenient substitute for extirpation (Marquis and Hilgard, 1936; Sterling and Miller, 1941).

Fifthly, different aspects of behaviour may well be differentially affected by the same drug at the same or different times. Gliedman and Gantt (1956) found that both reserpine and chlorpromazine had most effect on unlearned reactivity, moderate effect on the retention of learned motor activity and least effect on the retention of learned autonomic activity. Therefore a battery of diverse conditioning techniques should always be used; only this type of approach will permit of a complete description of the drug's effects on learned and unlearned behaviour. It would be premature to reject a new tranquillizing drug as ineffective because it did not weaken any one response that happened to be tested. For example, Hunt (1956), after some provocative observations about the essential similarities between the mechanism of imprinting in birds, emotional disturbance in man and the conditioned emotional response, points out that Meproamate may be an effective tranquillizer even though it does not block the sort of laboratory behaviour which most learning theorists would consider to depend upon a conditioned emotional disturbance or some form of aversive conditioning.

Sixthly caution must be exercised in the use and interpretation of *placebo* data. If, as has been suggested (Gliedman, Gantt and Teitelbaum, 1957; Trouton, 1957), a *placebo* response is a learned or conditioned response, then it is possible that the introvert will acquire and maintain *placebo* reactions more readily than the extravert. The confirmation of this interesting hypothesis would be of particular use to those interested in *placebo* effects as therapeutic measures. Seventhly, specific stimulants and depressants must be considered individually and their antagonistic effects must not be assumed without rigorous demonstrations. For example, the Newmans (1956) found that, in ordinary therapeutic doses, neither Dexamphetamine sulphate nor caffeine was effective in combating the depressant effect of alcohol as assessed by psychological and other tests.

Eighthly, many of the studies reported in the literature have been carried out on animals. Often the data were obtained from intensive investigations of a very few animals and often studies, which could otherwise be compared, have been carried out on different species. It is not surprising that, for these and other reasons, the findings are occasionally contradictory. This does not mean that animal research must invariably be suspect but merely that caution is required in making any generalizations. There are numerous examples of the value of such research and ample evidence that, despite an immense phylogenetic gap, the general principles of conditioning and learning under drugs apply in most species. Thus Dews (1956) found that central stimulants such as methamphetamine increased the pecking rate in pigeons in an operant conditioning situation, whereas phenobarbital tended to reduce this rate. And more recently, in the laboratory, Sinha, Franks and Broadhurst (1958), assuming alternation behaviour of rats in a maze to be a measure of inhibition, demonstrated clearly that this effect could be modified in the predicted directions by the administration of the appropriate amounts of stimulant and depressant drugs.

Differential Diagnoses

The use of conditioning techniques for descriptive, diagnostic and predictive purposes in the investigation of psychiatric disorders and treatment has been given insufficient attention outside the Soviet Union. Irrespective of any clearly formulated theory of conditioning it is possible to make good, if less efficient, use of conditioning procedures. In those few areas where the treatment takes the form of a direct application of conditioned response theory, the need for making use of conditioning in the selection of candidates and the prediction of success becomes even more apparent. Even if the assumption that an influential general factor of conditionability exists has eventually to be rejected, the possibility of predicting success in conditioning therapy by a particular test of conditioning need not be vitiated. However, in certain disorders treated along these lines, there is some slight empirical evidence to support the theoretical formulation that introverts condition well and extraverts poorly. Thus it has often been observed that psychopathy contraindicates success in conditioned aversion therapy with alcoholics. (Diethelm, 1955; Thimann, 1949.)

Gantt and his coworkers (Gantt, 1950; Reese, Doss and Gantt, 1953) used conditioning techniques to help establish a differential diagnosis between psychogenic and "organic" psychoses. There is much evidence to indicate that patients with organic brain disturbances find difficulty in producing and

maintaining conditioned responses (Fleck and Gantt, 1951; Gantt, 1938; Gantt and Muncie, 1942; Rees, Doss and Gantt, 1953). This seems to apply whether the brain damage is a result of accident, disease or psychosurgery and is apparent in a wide variety of pathologies, e.g. Korsakoff's psychosis (Gantt and Muncie, 1942; Reese, Doss and Gantt, 1953), congenital idiots (Krasnogorski, 1933), cerebral palsy (Bordley, 1956). The fact that a catatonic, apparently out of all contact with the external world, is better able to form conditioned reflexes than a brain-damaged patient who is apparently in much better contact with reality, opens up exciting avenues for eventual therapy with certain forms of psychotics.

In general comparatively little is known about the conditionability of psychotics. According to Shipley (1934) schizophrenics are the slowest to acquire conditioned responses, followed by manic-depressives, neurotics and normals. According to Kaufman (1953), conditioned responses formed in the past in schizophrenics may persist but new ones cannot easily be formed. The poor conditionability of certain schizophrenics can be predicted in terms of Pavlovian concepts and there is some supporting evidence (e.g. Franks, 1954; Howe, 1952). On the other hand there is rather more experimental evidence that certain schizophrenics condition as well or better than normals in a variety of modalities (e.g. Pfaffman and Schlosberg, 1936; Bender and Schilder, 1930; Spence and Taylor, 1952). These conflicting findings are paralleled by an, at least, equal degree of confusion in the consideration of other aspects of the behaviour of psychotics; there is apparently no valid integrating principle which will account for the many ways in which different groups of schizophrenics have been reported to differ from normals and neurotics.

Numerous attempts have been made to develop a theory of schizophrenia consistent with Pavlovian concepts but none have been altogether successful (e.g. Ivanov-Smolensky, 1925, 1927, 1928, 1954; Gordon, 1948). Kempf (1953), without any experimental evidence, writes of schizophrenia as "a socially conditioned disintegrative emotional disease." Kanner (1943, 1951) provides a more fully substantiated discussion of the behaviour of autistic children in terms of excessive conditioning and Timmer (1931) has undertaken the enormous, and perhaps unrewarding, task of relating Kretschmer's theory of temperament and psychosis to brain physiology and conditioning. It is possible that considerable advances will be made when the experimental, free operant conditioning techniques of Lindsley (1956), which use what is essentially a glorified Skinner box, are more fully developed.

Sensory Measurements

Pavlov's original salivation method is useless for measuring the hearing acuity of small animals and consequently special conditioning techniques, often far removed from those originally devised by Pavlov, have had to be developed (e.g. Goller *et al.*, 1953; Elder, 1934; Horton, 1933; Wever, 1930). Probably the best technique, in that it is objective, readily quantifiable and suitable equally for small animals and all human subjects, is that of Dworkin and his associates (Dworkin, Kutzman, Hutchinson and McCabe, 1940.) They have investigated the hearing threshold and hearing range in normal animals and in those which have undergone operation and extended the method to the study of pitch and intensity discrimination. The study of sensory discrimination in children has, with very few exceptions (e.g. Kasatin and Levikova, 1935), been neglected; especially such aspects as the development of discrimination as a function of age and of individual differences in personality.

Under certain circumstances the ability to form a conditioned response may be the only evidence that a small baby is capable of responding to specific forms of sensory stimulation (Aldrich, 1938). It is often the only objective method of determining the hearing acuity of infants, mental defectives and certain psychotics. Recently attention has been focused on P.G.R. conditioning as an indication of auditory responsiveness (Bordley, 1956; Hardy and Bordley, 1956). Numerous investigators (e.g. Bloomer, 1942; Ewing, 1944; Keaster, 1947; Utley, 1949) have reported conditioning techniques in which the child is trained by various teaching devices to respond to auditory signals. Of particular importance is the "Peep Show," developed by Dix and Hallpike (1947), in which a child is conditioned to press a button whenever he hears a pure tone in order to be rewarded with an entertaining picture.

Such techniques are not without their dangers, as a valuable study by Goldstein *et al.* (1954) amply demonstrates. They found that auditory conditioning was difficult to establish in aphasic children, whereas it was readily established in non-aphasic children. It is probable that it would be equally difficult to establish a conditioned hearing response in hysteric and extraverted subjects, as well as in children suffering from other forms of brain damage. In brief, if it is not first established that a child is capable of forming conditioned responses fairly readily, negative results can be highly misleading. There is little doubt that in the past, because factors of conditionability and personality were ignored, children have been falsely diagnosed as suffering from defective hearing by means of incorrectly used conditioning techniques.

A similar difficulty arises when malingers and

hysteries are being examined. Only if the experimenter is successful in establishing a conditioned response to a stimulus affecting an hysterically anaesthetized sense modality, are the results of value (Sears and Cohen, 1933). Thus Cohen, Hilgard and Wendt (1933), in the case of a patient believed to be suffering from hysterical blindness, were able to establish a conditioned eyelid reaction to a light source flashed in the blind eye even though the subject did not report seeing the light. These workers even succeeded in establishing conditioned verbal responses to a light flashed into the blind eye. It is sometimes suggested that conditioning techniques would be of value in differentiating between patients suffering from hysteria and from some form of cerebral damage. Since both these categories are likely to condition poorly it is impossible to use conditioning techniques in an attempt to establish a differential diagnosis until more is known about the specific response patterns of hysterics in various conditioning modalities and about the specific conditionability of brain-damaged subjects as a function of the area and extent of the damage and the nature of the conditioning stimuli.

Emotional and Psychosomatic Aspects

The phrase "conditioned emotional reaction" can be traced back to Watson and his colleagues (Watson and Raynor, 1928). Together with many other independent investigators (e.g. Jones, 1930; M. C. Jones, 1924*a*; M. C. Jones, 1924*b*), they successfully developed and eliminated conditioned fear responses in children. (Gantt 1953*a*) gives a graphic account of the conditioned fear response of dogs in the real-life, as opposed to the laboratory situation. Masserman (1943), placing his cats in a situation where hunger impelled them towards food at the same time as an air blast drove them away, claims to have produced what he called an "experimental neurosis," but what is probably better described as a conditioned emotional response. It is of interest that the technique used by Masserman to dispel the "neurotic" symptoms greatly resembles the technique of extinction in an orthodox laboratory conditioning situation.

Critics of such laboratory experiments sometimes argue that in "real life" emotional reactions persist for much longer than laboratory-generated conditioned responses and that consequently these reactions must be attributable to factors other than conditioning. Such pundits ignore the plenitude of evidence derived from experiments based upon drive reduction theory, in which the drive reduction itself is hypothesized to act as a reinforcing agent and so perpetuate the conditioned response pattern of behaviour. In this way it is possible to account for the continual repetition of the apparently useless act of the obsessive

compulsive, where the reduction of anxiety, itself a conditioned response, provides the necessary reinforcement to prevent the pattern from extinguishing itself. Another not incompatible possibility is that the conditioned response, by a process of stimulus generalization, gets reinforced in everyday life by numerous situations of varying degrees of similarity to the original conditioning stimulus. Watson is not alone in formulating a theory of conditioned emotions; similar is that of Skinner (1938), where emotion represents a change of reflex strength. Even Hull's concept is similar for, although he neither uses nor defines the concept of emotion, Hull apparently subsumes it under changes in drive strength.

Ample evidence has already been presented to suggest that anxiety is one of the most readily acquired and persistent conditioned reactions and one aspect of anxiety which has been most extensively investigated is the cardiac component. According to Gantt (1953a, 1953b), almost all conditioned responses possess a cardiac component which is more stable and more difficult to extinguish than the motor components of the conditioned response. This probably accounts, in part, for the wide pervasion of conditioned manifest anxiety; for example, conditioned tachycardia remains long after other components such as salivary conditioning have vanished. The fact that the "psychosomatic" aspects may be all that remains of an earlier conditioned response is regarded by Gantt as the basis of human conflict. The overt (motor) behaviour is adaptive, the cardiac and other autonomic conditioned components are not so easily extinguished. Thus there may be good *overt* adjustment to a situation but emotional conditioning from some previous situation is still present.¹

For these reasons Gantt and his colleagues have given particular attention to a study of both cardiac conditioning and the specific changes in heart rate which are said to accompany the conditioning of all reflexes (Gantt 1944). It has been demonstrated that a close parallel exists between the intensities of conditioned motor responses and the amplitude of the heart-rate changes (Robinson and Gantt, 1947); these changes even parallel the time intervals between the various motor conditioning stimuli (Gantt, Gakenheimer and Stunkard, 1951). The changes in heart rate during the establishment of a conditioned response sometimes take the form of an acceleration and sometimes a deceleration, depending on the individual. Why this should be so or to what factors it is related are at present only partially resolved problems. Whatever the reasons, the fact

remains that the heart rate is one of the most sensitive and accurate physical indicators of what is commonly termed emotional stress or anxiety (Weiss, 1956).

The conditioning of cardiac responses can be readily induced in most normal subjects to a variety of originally innocuous stimuli (e.g. Garvey, 1933; Minut-Sarokhtina, Sarokhtin, and Turgel, 1934; Scott, 1930). Tigerstadt (1926) showed that a conditioned cardiac response (an increase in blood-pressure) could be produced in humans merely by bringing the subject back into a previously exciting situation under which blood-pressure measurements had originally been taken and Anderson, Parmenter and Liddell (1939) have demonstrated the development of an experimental neurosis and accompanying cardiac disorder in the sheep. When Beir (1940) conditioned various cardiovascular responses to a buzzer, using exercise as the unconditioned stimulus, he found that the conditioned cardiac response became more and more intense as the reinforcements continued. It is hardly surprising that it has been estimated that between 20 and 50 per cent of all patients who consult physicians for cardiac disorders show no organic lesions and that cardiac neuroses, i.e. functional heart disorders, have been found in almost every kind of neurotic to a greater or lesser degree (Wahl, 1932; Wyckoff, 1928). Beier (1940), as a result of his experiments, suggests that such cases could be treated by a process of reconditioning or of experimental extinction. The success of Maier's work (1939), in which he produced and cured experimental "neuroses" in rats by conditioning techniques, lends support to this suggestion.

There is some evidence to suggest that certain human involuntary processes can be made amenable to voluntary control by means of conditioned response techniques. Voluntary control can be initiated by a verbal or subvocal stimulus and, according to Menzies (1937), even by merely recalling a certain visual pattern.

Abnormal perception may also be produced in a similar manner and Leuba (1941) describes the production of what he calls "images" by means of sensory conditioning under hypnosis. A bell and a pin prick were paired for several trials and the subject told to forget on waking. Later, when he heard the bell he felt uncomfortable sensations in his hand. Ellson's (1941) studies support Leuba's contention that conditioned sensations and hallucinatory images are equivalent phenomena. Lundholm (1928) produced both positive and negative conditioned responses; in one study, after inducing posthypnotic deafness he was unable to condition a sound to an electric shock. Not everybody, however, has been successful in the field of sensory conditioning. Cason (1939), who introduced the term, failed to obtain any

¹ Gantt (1953a) reports in detail the case of a dog who had lost all traces of the salivary and motor conditioned responses to food established two years earlier, but the cardiac component of the response remained undiminished.

positive results; so did Kelley (1934), in a well-planned experiment specifically designed to produce conditioned hallucinations. On the other hand it has been reported possible to condition critical flicker fusion, thermal sensations and even changes in gustatory sensations (London, 1954).

Weitzenhoffer (1955) suggests that somatic changes such as blister formation induced under hypnosis may be regarded as conditioned physical reactions and it is possible that subjects can even be placed in, and withdrawn from, an hypnotic trance by conditioning procedures (Narbutovich, 1934). There would seem to be little doubt that words can become conditioned to both internal and external stimuli, and in this way can precipitate various physical reactions (Bechterev, 1906; Platonov, 1930). The self-induction of trance states, and other associated bizarre physical phenomena prevalent in certain oriental and primitive communities, may well be explicable along these lines, even though the precise mechanisms are not as yet fully understood. The application of conditioning theories to problems in anthropology is not novel; in the early part of this century Frazer (1922), and later Kempf (1931), suggested a conditioned response mechanism by which sympathetic magic and taboo might become an effective process.

Bykov (Bykov, 1957; Eagle, 1933 and Gantt, 1953a) is supposed to have produced conditioned bile and urinary secretions and even the constriction of the blood vessels and changes in blood sugar. He is also supposed to have produced conditioned leucocytosis. However, Gantt, Katzenelbogen and Leucks (1937) failed to condition the rise in blood sugar after an adrenalin injection was paired with either a buzzer or the "preparation for the injection." But these authors note that hyperglycaemia can be produced under hypnosis merely by the suggestion: "You have drunk a glass of sugared water." Gantt (1953a) later extended this work to the conditioning of autonomic activities such as the vestibular function of equilibrium.

There is also some evidence that the sedation effect of depressant drugs such as Sodium Amytal can be conditioned (London, 1953) and, if Wilczowski's (1954) untrustworthy conclusions are correct (his experiment lacked both adequate design and statistical treatment), it is possible to condition the physiological effects of alcohol. Kleitman and Crisler (1927) conditioned the retching behaviour originally produced by morphine to a sound stimulus. Metalnikov and Chorine (1928) succeeded in producing conditioned serological reactions in animals, but Razran (1933) criticized their experiments on methodological grounds. When Smith and Dalinger (1933) carried out a similar, but much better-controlled, experiment the positive results were confirmed.

Experiments such as the above are of considerable

importance in the field of psychosomatic medicine, which is, unfortunately, one of the vaguest and most unscientific branches of psychology and psychiatry and one in which the literature is replete with anecdotal evidence, subjective impressions and dogmatic theory which rest on no adequate foundations. There is, however, a recent tendency in psychosomatic medicine to regard many somatic disorders such as allergies, peptic ulcers, mucous colitis, hypertension, etc. as conditioned response patterns of hidden origin (Friedman, 1951). The relationship between cortex and viscera is essential to an understanding of such disorders, and conditioned response techniques provide one of the most powerful tools for this purpose. Despite, in certain rare instances, egregious attempts to make their findings compatible with a rigid philosophic system, the data obtained by Soviet neurophysiologists are of primary significance. By combining electrophysiological and biochemical methods they have accumulated an impressive array of factual information which should not be overlooked on the above account (Liberson, 1957). It is claimed that bladder distension in man has been conditioned and also increases in metabolism; it is even claimed that conditioned diuresis has been established in a denervated kidney. There is ample evidence of EEG conditioning (*Proc. IV Int. Cong.*, 1957) and, more practically, of the conditioned inhibition of uncinate fits (Efron, 1957).

The wide variety of body functions which are capable of being readily conditioned has caused several workers to attempt to induce specific psychosomatic disorders by experimental means. There are for example, many indications that bronchial asthmatic attacks can be provoked by means other than direct contact with the specific noxious agent, i.e. various conditioned stimuli may be effectively substituted for the original agent (Kammerer, 1934; Mackenzie, 1885; Metsger, 1947). The Noelpps have carried out a recent series of experiments in which they provoked experimental asthmatic attacks in guinea-pigs by exposure to antigenic or histamine spray (1952, 1954). By pairing this procedure with a sound they were able to produce conditioned asthmatic attacks after as few as five reinforcements. Acting upon the observation that asthmatic attacks in humans often followed emotional events, Groen and his associates (Dekker and Groen, 1956; Dekker, Pelser and Groen, 1957) managed to induce asthmatic attacks by exposing their patients to artificially constructed emotional stimuli selected in each case from a survey of the specific clinical histories.

Despite progress such as the above, asthma still continues to be a subject of controversy and the building of a bridge between the psychogenic and the somatic schools of thought is far from complete

(Bastiaans and Groen, 1954). From recent reviews (Leigh, 1953; L. Rees, 1956) of the relevant literature, two facts clearly emerge. The first, that there is now considerable evidence that emotional factors are involved in the aetiology of certain cases of asthma and the second, that the relationships, if any, between fundamental personality attributes and dispositions towards asthma are still largely unestablished. Some investigators have claimed that asthmatic attacks have an hysterical basis while others report that the most common form of neurosis pertaining to asthma is that of anxiety (L. Rees, 1953).

Franks and Leigh (1958), in an attempt to throw light upon this problem in an objective manner, used the technique of conditioning coupled with personality questionnaires relating to introversion-extraversion. Although their asthmatic group was more neurotic than normal subjects, but less neurotic than non-asthmatic neurotics, they did not differ in conditionability from the normal group or from the group of neurotics, of whom half were dysthymic and half were hysteric. These results are consistent with the possibility, maintained by some allergists, that the common personality type assumed to be possessed by asthmatics is an effect and not a cause.

Psychogenic pain may be classed with the psychosomatic disorders. It is possible that such pain is a form of conditioned "suffering" which is interpreted as pain by the patient because it was associated with pain at one time. For example, when a dog has been trained to respond to a bell in anticipation of a painful shock, it displays symptoms of anxiety or suffering when the conditioned stimulus is presented; but there is no reason to suppose that the animal is actually experiencing pain (Wikler, 1948, 1950). Thus Malmö and Shagass (1950) found that random movements during intervals between exposures of their subjects to head pain were reduced following prefrontal leucotomy, although head withdrawals to the actual painful stimuli were not. It may be that leucotomy, which is known to reduce conditionability in certain cases, reduces the strength of conditioning of responses to the suffering associated with pain. This may be the possible mechanism underlying the effective reduction of intractable pain by surgical brain operations.

Conditioned Response Therapy

Sargant and Slater (1954) introduce their book with a sentence which is worthy of quotation: "It is a remarkable fact that, despite the popular notion that psychotherapy is the only method of treatment of psychological conditions, most of the big advances in psychiatric therapy have been along somatic lines." A frequent objection to such forms of treatment and, more specifically, to any application of conditioning

is that it is merely the symptom which is ameliorated and not the "underlying cause." Apart from the irrelevance of such a comment to a patient whose prime cause for complaint (and usually the initial reason for his referral) is reduced, there is an increasing body of experimental data which indicates that even the so-called "dynamic mechanisms" may be described and duplicated in a language system acceptable to the S-R learning theorist.

Probably the greatest contribution to the understanding of unconscious processes has been made by the experimental psychologists using precise and readily quantifiable data, rather than by the more speculative clinicians. Schoenfeld (1950), defining anxiety in terms of the behavioural changes following a signal of forthcoming noxious stimuli, has given adequate arguments for the use of conditioning in the experimental study of anxiety. Often anxiety is an unconscious process in so far as it is impossible to verbalize. Lacey and Smith (1954), operationally defining anxiety in terms of the psychological changes that occur in anticipation of an electric shock, preceded this shock by a spoken word and showed that human subjects could develop a conditioned anxiety reaction in which the subjects were *unaware* of the nature of the conditioning signal. In another series of experiments, Lacey and his colleagues (Lacey and Smith, 1954; Lacey, Smith and Green, 1955) asked a group of normal subjects to chain associate for fifteen seconds to a list of forty different stimulus words. One of these words (differing for different subjects) was followed by an electric shock. They found that conditioned anxiety responses to verbal stimuli could be obtained often with as few as two reinforcements.

More recently the Staats (1957), testing an hypothesis that meaning itself is a kind of response and consequently capable of being conditioned, associated nonsense syllables with *different* words having a certain similarity of meaning. They were eventually successful in conditioning the common meaning components of the different words to the originally neutral nonsense stimuli. This study is of considerable importance for those who, with Mowrer (1954), view speech as a conditioning device and meaning as a conditioned response. It is significant that in the studies of Lacey a conditioned response appeared not only to the conditioned stimulus, but also to other stimuli meaningfully related to this stimulus. For example, if a conditioned response is obtained to the word "style" then semantic generalization may be found to both the homophone "stile" and the synonym "fashion."

Not only may meaning be conditioned without awareness but overt behaviour may be modified without the subject's knowledge. For example

McNair (1957) has shown that the rate of verbal responding can be influenced without the subject's awareness by altering the rate of reinforcement. Nuthmann (1957) found that the experimenter's saying "good" was able to function as a reinforcement for the conditioning of "acceptance of self" on a personality questionnaire relating to personal attitudes—this also without the subject's awareness. Hildin and Brown (1957) gave a questionnaire by telephone and obtained similar results using "good" as a reinforcer.

In a remarkable laboratory parallel of clinical repression, Ericksen and Kuethe (1956) extended these findings to show that conflict behaviour could be modified. They experimentally demonstrated avoidance conditioning without awareness by punishing certain arbitrarily selected words in a subject's chain association during a word association test by an electric shock and found that these words were "repressed" in the consequent test trials on the same word association test even when the threat of shock was absent. This study is atypical since it is one of the very few in which an experimental analogue of a dynamic concept successfully satisfies all the generally accepted criteria of the concept.¹

Studies such as these are of importance in the application of conditioning principles to the treatment of patients by some form of psychotherapy since most psychotherapists work on the assumption that a behaviour reaction on their part can modify or influence their patient's behaviour. But this section is primarily concerned with the direct application of conditioning techniques in situations other than verbal. In this respect conditioned aversion therapy, in which a conditioned aversion is established by the use of some noxious unconditioned stimulus such as nausea or an electric shock, is probably the most widely recognized technique.

From a recent excellent review (Solomon and Brush, 1957) of avoidance conditioning and anxiety as the reinforcer for the learning of new responses it is clear that, apart from the treatment of alcoholism, electric shock is the most widely used aversion motivator. By this means all kinds of conditioned aversions can be produced in both animals and men. Probably because electric shock has many advantages, such as minimal adaptation properties and maximal control, the possibilities of utilizing in man other averting stimuli such as bright lights, loud noises,

heat spots and jets of air have been singularly neglected. Furthermore, the relative efficiencies of classical and avoidance types of aversion conditioning and the problems involved in the treatment of mental disorders by these means are still largely open questions.

Alcoholism is frequently treated by some form of conditioned aversion therapy, in most cases using apomorphine as the conditioned stimulus. Although there is a plethora of studies purporting to evaluate the effectiveness of such techniques (Franks, 1958a), the majority are of limited value in arriving at any conclusions. Firstly, despite minutiae of descriptive material, reports provide insufficient technical and procedural details of the methods used; secondly, although lip service is usually paid to the need for rigorous experimental techniques, few take this advice. It is consequently difficult to assess the potential value of conditioned aversion therapy for alcoholism carried out according to strict experimental schedules.

Many problems are associated with the use of apomorphine as the unconditioned noxious stimulus. For example, it has been demonstrated upon many occasions that centrally depressant drugs make the learning of new conditioned responses more difficult. If apomorphine is in this category (and no one has yet investigated this important problem) then it is clearly the most unsuitable drug to use alone as a noxious agent. Several solutions suggest themselves; it may be possible to find a noxious agent which is not a central depressant; it may be possible, prior to each session, to give the patient a stimulant drug such as caffeine to counteract the depressant, but not the nausea-producing action of the apomorphine. The concept of combining the apomorphine with some other agent is no new one, but the combinations suggested have not always been propitious; for example, Lemere and O'Hallaren (1949) propose to administer *sedatives* during the course of treatment to relieve tension.

It should be pointed out that the judicious use of additional pharmacological agents to augment the conditioning process apply equally to other forms of conditioned aversion therapy such as the treatment of fetishism (Raymond, 1956) or writer's cramp (Liversedge and Sylvester, 1955). Indeed, if psychotherapy is conceptualized as an exercise in learning and conditioning, then it might be considered advisable to give a depressant drug during the extinction of the undesired learning or habit pattern and a stimulant drug during the more positive or training part of the treatment. Sargant and Slater (1954) cite many examples of the use of Sodium Amytal for the reduction of manifest anxiety and in this context describe the drug as useful for "deconditioning to situations likely

¹ In the animal world regression has been demonstrated by, among others, Mowrer (1940) and Masserman (1943, 1946). An animal is first taught to obtain food by a simple reaction pattern. This conditioned pattern is then extinguished and a more complicated food-getting reaction pattern is developed in its place. If this more complex conditioned pattern is now associated with an electric shock or sudden blast of air the animal tends to "regress" back to the earlier and apparently extinguished learned pattern of response.

to produce anxiety." If anxiety is regarded as a conditioned response pattern of behaviour this would seem to be an admirable procedure. A preliminary attempt to make use of drugs in these ways is reported by Agostan (1944), although his theoretical orientation is extremely different to that presented here.

If apomorphine does behave as a depressant a quite different solution would be to make use of agents other than drugs as the noxious unconditioned stimulus, perhaps shock. Using this technique, Kantorovich (1929) was able to induce a conditioned aversion not only to the taste of alcohol, but also to its smell and sight and even to a photograph of a bottle.

Alcoholism and other addictions are frequently regarded as tension reducing and pleasure generating activities.¹ If it is correct that numerous physiological reactions, drug effects and internal secretions can be conditioned, then it might be possible to condition certain of the unconditioned physiological effects of alcohol and other drugs to innocuous conditioning stimuli. Furthermore, if many of the psychological effects of alcohol are conditioned responses to the sight, taste or smell of alcohol as a conditioned stimulus, then it should be possible to produce these same conditioned responses to more innocent and less harmful conditioning stimuli than alcohol. In this respect, Lindesmith (1947) comments that although the first stab of a hypodermic needle is painful to the morphine addict it rapidly becomes a conditioned stimulus to which the conditioned response is pleasure, and the subject then actually enjoys the entry of the needle. In one patient of Lindesmith's this response was so well established that he reacted to the injection of a saline solution as if it were morphine for as long as fifteen consecutive days. These techniques might be of value in counteracting the addiction withdrawal symptoms often experienced whatever form of therapy is used. Rubenstein (1931), using a similar procedure, was highly successful in the treatment of a chronic morphine addict.

After the treatment of alcoholism, the next most frequent use of direct conditioned aversion therapy is probably for the amelioration of various enuretic symptoms in children. Since the technique was reintroduced by the Mowrers (1938) many investi-

gators have reported successful results, but always with small samples. However, Martin and Kubly (1950) report a 74 per cent success with a total sample of one hundred and eighteen children. Most of the apparatus commercially available consists of some form of conductor, coiled or in two sections so that there is an insulating blanket or pad preventing the completion of the electrical circuit. When the child urinates the circuit is completed and a buzzer sounds. The buzzer acts as the unconditioned stimulus, waking is the unconditioned response which it is hoped to condition and bladder tension is the conditioned stimulus. The ultimate aim is for sphincter control, by a process of generalization, to become the eventual conditioned response. Although such a pattern can be established even before an infant can sit up, i.e. prior to effective voluntary muscle control, for a variety of reasons the technique is not advisable at this early age (Fleck, 1953; Kanner, 1943).

The aetiology and treatment of writer's cramp is currently a matter of much dispute. According to Liversedge and Sylvester (1955) the persistence of writer's cramp, whatever its origin, may be attributable to the formation of a conditioned response. Proceeding on this assumption they successfully treated a number of cases which had previously proved to be resistant to diverse kinds of psychotherapy. Whenever the subject's hand trembled in threading a metal stylus into a series of progressively smaller holes in a sheet of metal he received a mild electric shock, similarly whenever the subject was unable to trace various cursive patterns with a stylus, or whenever his muscles contracted and applied excessive pressure to the handle of a fountain pen, he also received a shock. The advantage of this type of therapy is that it can be given by anyone with sufficient understanding of the mechanical nature of the disorder to apply the various training exercises.

Considering the unimpressive record of psychotherapy, no possible techniques can be reasonably ignored, especially when the proposed techniques are based on some rational and testable formulation.¹ A particular example of the partial failure of the more conventional forms of psychotherapy is that of the treatment of the sexual disorders. As early as 1927 Kostyleff (1927) favourably contrasted conditioned reflex mechanisms with Freudian principles in the aetiology and treatment of sexual perversions. More recently, Gordon (1948) developed an extended conditioned reflex treatment of abnormalities such as incestuous attachments, fetishism, exhibitionism and scopophilia, and Salter (1949), in his characteristically

¹ The case has been argued elsewhere (Franks, 1958a) that alcoholism is itself a conditioned disorder, the possible sequence of events being something like this: initially an individual drinks in a social setting and the alcohol, by a process of classical conditioning in accord with the principle of contiguity, becomes associated with the relief of tension and anxiety resulting from being with friends. Now, to account for the perpetuation of the habit in most situations, simple conditioning is inadequate and it is necessary to invoke a reinforcement theory; the alcohol reduces the anxiety and it is this drive reduction which provides the reinforcement for the pattern of drinking to perpetuate itself.

¹ The insuperable logical paradoxes of Freudian theory are presented nowhere more clearly than in the many publications of Mowrer (*see* Mowrer 1953). The false claims of the psychoanalysts were exposed in the American psychiatric literature as long ago as 1933 (Sachs 1933).

vigorous if flamboyant manner, attempted to explain how masochism may arise as a conditioned response and be treated accordingly. A striking apparent success is reported by Raymond (1956) who, after a discussion of fetishism as a conditioned disorder, treated and cured a chronic and severe fetishist by the use of a noxious conditioned aversion technique.

A novel area where the direct application of conditioned response techniques has been shown to

be of some value is that of the treatment of bruxism (teeth grinding and gnashing during sleep). While the patient is in a deep hypnotic trance a conditioned response is established of waking from sleep as soon as the muscles of mastication begin to contract and start the grinding operation (Kuehner, 1956). Probably, as with enuresis and writer's cramp, it would be possible to develop a practical technique by means of which a conditioned aversion pattern of waking could be established without resort to hypnosis.

CONCLUSION

The methodology of conditioned reflexes has contributed much valuable information to the understanding of human behaviour and is a most promising tool in the formidable task of establishing an objective science of abnormal psychology. The many implications discussed in the major portions of this chapter bear witness to the exciting opportunities which this area of abnormal psychology can provide.

The contribution might have been greater had more concern been attached to those criteria which the present writer considers to be essential requisites of acceptable research (Franks 1957c). In this respect a marked contrast exists between the usually exemplary studies of the more academic investigators concerned with fundamental problems of learning theory or neurophysiology, and the quixotic, but frequently unsystematic and ill-conceived, experiments of the clinician and the applied psychologist. Many potentially important experiments are of limited value because of inadequate design and a lack of rigour in their execution; in some instances an insufficiency of technical or procedural details precludes any valid evaluations being made.

These are all necessary, but not sufficient, requirements for the emergence of a science of abnormal psychology which makes full use of conditioned response techniques and data. In addition, there is a need for some resolution of the problems fleetingly introduced in the first section of this chapter. In particular, the concept and inclusiveness of the term *conditioned response* requires much clarification. There is little doubt that the simple Pavlovian model, inviting as it is, is inadequate to account for all the facts, and it is probable that eventually conditioning and learning must be integrated into one comprehensive system.

The theory of conditioning and personality promulgated here suffers from many temporary weaknesses, not least of which are a present lack of extensive confirmatory data and the possibly premature assumption of a general factor of conditionability, the reality of which has yet to be demonstrated.

Although there is no *a priori* justification for this assumption (the principle of cortical equipotentiality no longer being tenable), the data presented in the present chapter are in agreement with the existence of either a general factor, or of several group factors, or even with both possibilities.

A further weakness, unfortunately common to almost all studies involving personality variables, is the diminutive magnitude of the obtained correlations between conditioning and those measures of personality to which conditionability is believed to be related; a possible explanation (when problems of test reliability, etc. have been excluded) is that the general factor, if it exists, is insufficient to account for an individual's ability to generate and retain conditioned responses. Other specific factors, at present unrecognized, may play a much larger role in the formation of conditioned responses than has hitherto been suspected. Another weakness of the present theory is that certain of the findings may relate not to classical conditioning, as it is generally (but not universally) defined, but only to behavioural changes at the peripheral levels. This is especially possible in those studies dependent on modifications induced by the actions of drugs and in those studies which attempt to relate largely peripheral phenomena, such as dark adaptation, to conditioning (Granger and Franks, 1958).

Nevertheless, the present theory provides many fundamental advantages which more than compensate for the existence of numerous weaknesses, none of which are devastating and all of which can be remedied. The theory is so formulated that it permits of predictions which may be explicitly tested in a variety of different situations and with a variety of conditioning techniques. Furthermore, it forms part of a much more extensive theory of human behaviour (Eysenck, 1957), in which the conditioned response is merely one aspect of the manner in which the central and autonomic nervous systems manifest their functions.

It is very likely that conditioning alone is insufficient

to account for all forms of normal and abnormal personality development. As Pavlov insisted, the conditioned response is one possible technique, certainly not the only one, for understanding the principles of central functioning and the ways in which the general laws of central activity manifest themselves. The findings derived from conditioned response experiments can therefore be integrated with the increasing number of predicted findings obtained in many different contexts and with many different techniques, beyond the scope of this chapter, but not of this volume.

In conclusion, it must be reaffirmed that both the general theory of personality and the specific aspects pertinent to conditioning will require much modification and much elaboration. However, the extreme probability that the theory, in its present form, is at best a simplified version of the true state of affairs, is not of necessity a disadvantage; the more complex the formulation in the initial stages, the more difficult it is to devise a series of crucial experiments. As Morris Cohen (1944, p. 182) puts it: "If, *per impossibile*, any theory were as complex as the actual facts, it would have no real value. All theory is a simplification and therefore incomplete."

CHAPTER 13

Learning and Abnormal Behaviour

H. GWYNNE JONES

INTRODUCTION

EXPERIMENTAL work on learning has given rise to a number of generalizations concerning lawful relationships between variables which, stated in neutral terms, would be accepted by proponents of most "theories," although their interpretation would vary from theorist to theorist. Unfortunately, the majority of these generalizations were derived from laboratory experiments with animals, particularly the rat, and their application to human behaviour is frequently an essentially unvalidated argument by analogy. The circumstances of human learning, however, even in a laboratory, are frequently so unlike those in experiments with animals that the analogy becomes obscure and predictions based on empirically established relationships may be transferred from one situation to the other only if the experimental variables be first translated into the terms of higher order theoretical concepts, which may then yield new first-order factual predictions in the new situation. Hull's theoretical system (Hull, 1943, 1951, 1952), by virtue of its ambitious scope, lends itself most easily to this process: his premature attempt at strict quantification, which has produced some of the most damaging criticism of his viewpoint (cf. Koch, 1954), is the least necessary aspect of his theory for this type of extrapolation. With some modifications, this chapter will be written largely in Hull's terms although it is hoped that its substance could be expressed in the terms of several alternative theories.

Two specific modifications of Hullian theory, adopted for the purposes of this chapter, need particular mention. The first relates to the concepts of "reactive inhibition" and "conditioned inhibition," which may be particularly relevant to abnormal psychology. Hull's systematic use of these concepts

is illogical in certain respects and the writer's modification of the basic Hullian equation (Jones, 1958*b*) is adopted in order to avoid these difficulties. Thus Hull would express the relationship between "net reaction potential" ($s\bar{E}_R$), "habit strength" (sH_R), "drive" (D), "reactive inhibition" (I_R) and "conditioned inhibition" (sI_R) as—

$$s\bar{E}_R = f(D \times sH_R) - (I_R + sI_R)$$

whereas the present alternative is expressed as—

$$\begin{aligned} s\bar{E}_R &= f(D - I_R) \times (sH_R - sI_R) \\ &= f(D \times sH_R) - (D \times sI_R) - (I_R \times sH_R) \\ &\quad + (I_R \times sI_R) \end{aligned}$$

The second major modification relates to Hull's inclusion of classical conditioning and instrumental learning within the same theoretical framework. It is considered that evidence derived from experiments such as those of Mowrer and Solomon (1954) and Mowrer and Aiken (1954) is sufficiently strong to justify the adoption of a dualistic theory, as advocated by Skinner (1935), Schlosberg (1937) and Mowrer (1947, 1950), in which Pavlovian conditioning by contiguity is equally effective with trial-and-error learning reinforced by drive reduction. Mowrer's view that conditioning relates only to the learning of responses mediated by the autonomic nervous system is not essential to such a theory, nor is any other particular response classification, though Welch's (1955) argument that conditioned responses are essentially involuntary has considerable force. Classical conditioning as such, has been treated in the previous chapter but aspects of its interaction with other learning processes will need to be considered further.

LEARNING AND NEUROSIS

Aetiology

Genetic factors have been shown to play an important role in determining the vulnerability of an indivi-

dual to neurotic breakdown (cf. Chapter 8 of this HANDBOOK by Slater and Shields) but the actual behavioural disturbance probably results from the

imposition of some form of environmental stress on the individual concerned. Learning is essentially the modification of an organism's behaviour resulting from its interaction with a changing environment and, for any learning process, the nature of the behavioural change will be partly determined by the genetic constitution of the organism. Therefore, in a sense, a neurotic breakdown may be described as learned, or learning processes may be important in its development. Certainly an aetiological theory of neurosis expressed in terms of learning concepts provides valuable links between abnormal and general psychology, and the possibility of experimental validation in laboratory situations.

Some symptoms may well result from the conditioning of a naturally occurring somatic reaction to incidental stimuli. Russian studies, described by Bykov (1953), clearly indicate that reactions of the circulatory, respiratory, urinary and other systems do become conditioned in everyday life situations. Thus, for example, refrigeration workers adapt physiologically to the low temperature within seconds of entering their workroom. The same physiological changes occur with similar rapidity if the room is entered when at a normal temperature, but if these workers are subjected to cold conditions in novel surroundings their adaptation time is no shorter than that for individuals without their experience of cold conditions. In this example the conditioned responses are entirely adaptive but it is conceivable that similar processes may lead to the development of non-adaptive psychosomatic symptoms. In similar fashion, an abnormal or disease reaction may be brought under the control of a range of originally inadequate stimuli thus giving a truly somatic symptom a "psychic" overlay and enabling it to become "triggered off" by processes generally recognized as psychological in nature. Consistent with this analysis, Metcalfe (1956) and Dekker and Groen (1956) have experimentally demonstrated the conditioning of attacks of asthma to such diverse stimuli as the photograph of a horse and a patient's mother in patients who were also sensitive to allergens.

Other symptoms may result, not from the learning of an unadaptive response, but from the failure to learn an adaptive response. Thus, in the course of maturation, a child learns not to urinate whenever his bladder is full but to inhibit this response in all but certain fairly specific environmental situations. At a later stage, these conditioned inhibitions are sufficiently well established to continue functioning during sleep. For the nocturnal enuretic, however, this degree of learning is not achieved or breaks down relatively easily.

While some symptoms may be such functionally discrete entities it is probable that the majority

represent one facet of a more general neurotic disorder, which several authors would account for in learning terms (Shoben, 1949; Dollard and Miller, 1950; Mowrer, 1950; Cameron and Magaret, 1951; Wolpe, 1952; Skinner, 1953; Eysenck, 1957; Jones, 1958a). The majority of these agree with Freud (1926) in allocating to anxiety a central role in the maintenance of neurosis but they conceive of anxiety as a conditioned fear reaction, including affective and respondent components and possessing aversive drive properties. In its role as an acquired drive, anxiety will energize, and by its reduction, reinforce various aversive instrumental responses of the organism. As a powerful and massive response involving central, skeletal, autonomic and hormonal systems, anxiety will disrupt the ongoing reactions of the organism. As pointed out by Schoenfeld (1950), the application of the term "anxiety" to this particular concept is unfortunate in that it already carries many different connotations (cf. May, 1950). A more neutral term such as "conditioned emotional response" (C.E.R.) or "conditioned avoidance drive" (C.A.D.) would be more appropriate and include many experientially different phenomena such as "anxiety," "guilt" and "disgust."

The mediating role of a C.A.D. is best illustrated by a consideration of traumatic avoidance learning in animals (Solomon and Wynne, 1954; Solomon and Brush, 1956). If an animal, confined in a suitable apparatus, is presented with a neutral stimulus followed by a powerful electric shock, a massive pain-fear response involving central, neuro-endocrine and autonomic reactions ensues and the animal makes various aversive skeletal responses, of which some, if the apparatus is appropriately constructed, will terminate the shock and may, therefore, be described as escape responses. If, after one or several such trials, the animal is replaced in the apparatus, indications of fear are evident in response to the conditioned stimulus and before the onset of shock. This indicates that the fear reaction has become conditioned to this previously neutral stimulus and the C.A.D. may be measured by its disorganizing effect on unlearned or previously learned responses. With further trials in the original situation the escape responses tend to occur in response to the conditioned stimulus: escape from shock gradually or suddenly becomes avoidance of shock. Avoidance responses developed in this way, unlike the more usual instrumental responses of learning experiments, may be maintained throughout hundreds of extinction trials without the readministration of shock. According to the mediation hypothesis, this derives from the fact that reinforcement does in fact occur owing to a reduction of the C.A.D. by escape from the conditioned stimulus. Murphy, Miller and Mirsky (Murphy *et al.*, 1955;

Miller *et al.*, 1955; Murphy and Miller, 1956), by means of an ingenious series of experiments with monkeys, have shown that a C.A.D. can be acquired by animals with no personal experience of shock but by seeing a stimulus animal receive shocks. These workers also demonstrated the generalization of avoidance responses to social non-experimental situations by the modification of social dominance hierarchies.¹

To explain the failure of extinction of the C.A.D. itself Solomon and Wynne (1954) have adduced two additional principles. The first, the principle of *anxiety conservation*, postulates that, by an early avoidance reaction, the conditioned stimulus is removed before the long-latency C.A.D. recruits to its full amplitude, thus protecting it from extinction. If, from partial extinction, the avoidance response latency increases, the C.A.D. develops fully, reinforcement occurs and the avoidance latency again decreases. Secondly, they postulate that severe trauma causes irreversible physiological changes which bring about a *partial irreversibility* of the C.A.D. resulting from such traumata. This paper reports evidence consistent with the principle of anxiety conservation, but Solomon and Brush (1956) express less confidence in its validity owing to failures to observe the expected relationships between the latencies of avoidance responses and physiological measures of emotional arousal. Reactions such as accelerated heart rate, however, are likely to be only partial components of the complex drive state and not necessarily correlated with the strength of the aversive tendency. If valid, this principle would ensure that evocations of the C.A.D. could never be "massed" and are, therefore, less liable to extinguish. Selye (1955) has shown that the chains of responses to traumata include hormonal releases deleterious to the tissues of the organism. The conditioned reaction, if allowed to develop fully, might also include similar endocrine responses and thus reinstate the original reinforcement conditions. In this way a "vicious cycle" would be established, consistent with the irreversibility principle.

(The animals in traumatic avoidance learning experiments do not usually develop behaviour which could be described as "experimental neurosis." This is to be expected because the escape and avoidance responses are successful and the C.A.D. is playing an adaptive mediating role. Wolpe (1952) and others have shown that, when animals are subjected to traumatic shock from which they are unable to escape, marked behavioural disturbances occur, which may be claimed to merit the title "neurotic" in that they are unadaptive and persist through a considerable period of time outside the experimental situation.) These represent various persistent auto-

nomic and skeletal responses which originally occurred in response to the shock and which markedly increase when stimuli associated with the shock situation are presented to the animal. Mowrer and Viek (1948), by means of an ingenious experiment, have shown that such abnormal responses in animals are not a function of the increased duration of shock when avoidance or escape is impossible but rather of the fact that no effective avoidance response may be established on the basis of C.A.D. reduction.

Physical pain of traumatic dimensions may be used as an extreme and prototypal example of environmental stress and, hence, traumatic avoidance learning may serve as a paradigm of the dynamics of learning mediated by a C.A.D. Wolpe (1952) points out that a series of mild electric shocks have effects equivalent to a single powerful shock and postulates a mechanism whereby the strength of a C.A.D. may progressively increase (cf. Chapter 19 of this HANDBOOK by P. Broadhurst). The complexity of this summation effect is evident from the work of Bindra and Cameron (1953), who showed that for human subjects a rest interval, during which no shocks were received and the conditioned stimulus was removed, had an "incubation effect," leading to an increased C.A.D. as measured by galvanic skin responses and impaired discrimination between "shock" and "non-shock" signals after the interval.

In human development, of course, a large number of aversive situations other than direct painful stimulation are common as illustrated by reports on individuals with congenital insensitivity to pain. Cohen *et al.* (1955) describe such a person and report her startle responses to sudden stimuli. West and Farber (1957) consider several cases and conclude that pain is not the exclusive precursor of a C.A.D., nor of the control required for socialization. They comment that a child of this type cries just as hard when spanked as does a "painful" child. Similar points are made by McMurray (1955) from a review of many cases but he is inclined to reject secondary drive theories of human motivation. Many traumatic situations for humans derive from the socialization process wherein individuals undergo a training in which socially unacceptable aspects of their behaviour, which are often strongly motivated, are punished by parents and the formal agents of society. The conflicts between powerful but incompatible response tendencies involved in such situations may be important in the generation of stress. Miller (1944), on the basis of experimental studies of conflict, claims that these remain unresolved only when avoidance motivation is operative and when the subject is retained in the area of conflict by physical limitations and other sources of avoidance, or the avoidance stimuli are ubiquitous or internal to the subject. Frustration, in

the sense of the blocking of a path to a goal or of consummatory responses at a goal situation, may also give rise to aversive "emotional" reactions (Brown and Farber, 1951) but the interpretation of experiments on frustration is as yet too controversial to permit of a ready application to problems of human behaviour (Marx, 1956; Seward, 1956).

From such situations C.A.D.s may well develop in a manner similar to that described for traumatic learning in animals. Childhood may be a particularly vulnerable period in that it is a period of intense socialization, the undeveloped nervous system is more reactive and plastic, the possibilities of effective avoidance are less and C.A.D.s may become attached to a wider range of conditioned stimuli owing to lack of learned perceptual discriminations and the absence of refined discrimination through language development. This is not to say that a C.A.D. may not, however, develop at any period of life when new stresses appear.

On the basis of such a theory, the behavioural disturbance described as neurotic may be analysed into two types of response; (1) the C.A.D. or anxiety response itself which will have visceral, skeletal and nervous components, and (2) various instrumental responses by which the conditioned stimuli are removed and hence the C.A.D. reduced. Both are learned behavioural responses and, as such, are symptoms of the neurosis: their division may parallel the Freudian distinction between the underlying neurosis and its symptoms.

With respect to the conditioned stimuli involved, these may derive from three sources: the punishing agent itself, for example the parent, when disturbances in relation to individuals in authority may result; the incidental environmental stimuli at the time of stress, when disturbances of the nature of phobias may be expected; the stimuli involved in the individual's own behaviour at the time of stress as, for example, when a neurotic subject fears to express aggressive impulses. The latter type of conditioned stimulus is the least likely to be avoided successfully as it is, in a sense, self-generated. As such, it may give rise to a type of neurosis particularly difficult to treat. This type of conditioned stimulation is the only one considered in their analyses by the most influential theorists in this field: Dollard and Miller (1950) consider that, in these circumstances, the neurotic solution is to inhibit the offending behaviour whereas Mowrer (1950) believes that the illicit response occurs but the consequences are avoided by various devices. In reaching these conclusions these writers fail to note that either adjustment, or maladjustment, is possible and rely on their apparently conflicting clinical experience. Whichever solution does in fact occur in the particular situation may be due to the

circumstances of original reinforcement, that is according to which of several responses made was effective in reducing the C.A.D. Alternatively, and more probably, in the light of recent work, innate individual differences may largely determine the nature of the response.

Whatever the original conditioned stimuli, by the well established process of stimulus generalization, a range of stimuli will later evoke the neurotic behaviour. If these present themselves with considerable frequency the disturbance may well become chronic. Frequently the eliciting stimuli on various specific occasions may appear to an observer to be entirely dissimilar and extremely unlikely to occur on any single generalization continuum. This may well result from secondary generalization (Hull, 1943). Thus, if an animal, via the mediation of a C.A.D., has learned to avoid a black circle, it will, by generalization, also avoid a white circle. The avoidance of the white circle will itself be reinforced by C.A.D. reduction, and by a second generalization, a white square will now be avoided, though this stimulus has neither its squareness nor its whiteness in common with the original conditioned stimulus. Verbal links may also, in human beings, produce similar effects (Lacey and Smith, 1954; Lacey, Smith and Green, 1955).

Many of these processes may be, in a sense, unconscious in that several experiments (e.g. Sidowski, 1954) have shown that a response may be conditioned to a stimulus or class of stimuli while the subject is unaware of any connexion or of any reinforcing process. Lacey and his co-workers (Lacey and Smith, 1954; Lacey, Smith and Green, 1955) have shown this to be true of C.A.D. responses and also that "unconscious" conditioning tends to produce less adaptive and more generalized C.A.D.s. Thus it is likely that a "dangerous" topic of conversation may be avoided just as experimental stimuli are avoided and this may also apply to symbolic responses or "thoughts," thus bringing phenomena such as "repression" within the same conceptual scheme. From this point of view, however, the unconscious does not acquire any special "dynamic" attributes (*see* Chapter 7, by J. Inglis).

Somatic reactions may play several roles in such a dynamic system. The total C.A.D. response involves somatic components and such psychosomatic symptoms as frequency of micturition may be direct expressions of a chronic or recurring C.A.D. state. Other somatic symptoms may represent avoidance responses which enable the patient to evade conditioned stimuli and, therefore, to reduce the C.A.D. Hysterical blindness or paralysis most obviously fit this pattern but similar dynamics may underlie a wide range of symptoms.

Individual Differences: Theory

Individual differences will greatly affect the course of events in any individual case but these have been largely ignored by most of the theorists previously mentioned, who tend to assume an extreme environmentalist viewpoint. Dollard and Miller, for example, consider the existence of neurosis an automatic criticism of child-rearing practices in our culture. There is, however, ample evidence for a wide range of relevant individual differences both physiological and psychological in nature. Lacey *et al.* (1953) have shown that individuals display a reliable pattern of autonomic responses to any particular experimental stress situation and that this pattern varies from situation to situation and from person to person. Malmo and his associates (Malmo and Shagass, 1949; Malmo, Shagass and Davis, 1950) report evidence consistent with the view that different physiological mechanisms (autonomic or motor) are specifically susceptible, in different individuals, to activation by stressful experiences and are related to the symptoms shown by such individuals when psychiatrically disturbed (cf. Chapter 11 by I. Martin).

The dimensional system of "neuroticism" and "introversion-extraversion," described in an earlier chapter, is a useful framework within which to consider individual differences of a psychological character and one which Eysenck and his co-workers (Eysenck, 1955, 1957) have linked to the type of general theory outlined here. Neuroticism, or vulnerability to neurosis, in terms of such a theory, implies low tolerance for stress, whether it be physical, as in painful situations, or psychological, as in conflict or "frustration" situations. In learning theory terms, an individual scoring high on the factor of neuroticism would be characterized by a high level of drive in avoidance situations. High appetitive drives are not necessary to the theory and it may be that the high drive of neurotics is aroused only in situations of threat or "ego-involvement." Evidence is lacking concerning the drive level of neurotics in reward situations but there is considerable evidence that, compared with normal subjects, they exhibit lowered response thresholds to painful stimulation (cf. Hall, 1953). The interpretation of pain-reactivity experiments is, however, difficult as the responses involved are frequently voluntary in nature and the thresholds measured do not necessarily correlate with physiological pain thresholds. To date, however, direct measures of the latter are not available. The presentation of a stimulus tending to evoke different, equally strong and incompatible responses might well be considered an experimental paradigm of a psychological conflict situation. Experimental work on "intolerance of ambiguity" is therefore relevant to the present argument. Hamilton (1957*a*, 1957*b*) reports

that anxious, obsessional and conversion hysteric groups of neurotic patients, while showing inter-group differences in the extent and manner of their avoidance, were all more intolerant of ambiguity than was his control group of normal subjects.

Eysenck's (1955, 1957) dynamic interpretation of the introversion-extraversion dimension in terms of individual differences along a neurological dimension of excitation-inhibition has been discussed fully in the previous chapter. It will suffice here to comment that the formal postulates, though based on Pavlovian notions, are stated in terms of differential susceptibility to "reactive inhibition" as conceived of by Hull. Correlated tendencies to inhibition of a more widespread and prolonged character are, however, implied in his expectation that neurotic extraverts (hysteries) will display symptoms of an inhibitory nature such as paralysis, amnesia, and anaesthesia while neurotic introverts (dysthymics) will present excitatory symptoms such as rumination, rituals, tremors, etc.

If such an interpretation of neurosis and neuroticism in learning theory terms is valid, the individual differences postulated should be reflected in the responses of experimental subjects in learning situations but, for unequivocal predictions from the theory to be made, it is necessary for the design of an experiment to include the systematic variation or measurement of at least the following variables: (1) the avoidance value of the stimulation presented (degree of stress); (2) the subjects' positions on the neuroticism dimension; (3) the subjects' positions on the introversion-extraversion dimension. The latter measures are seldom both available and the first is not yet possible: despite an increasing general interest in stress situations in recent years no satisfactory "stressor" metric has yet been achieved. Thus, in most instances, experimental results can be examined only for general consistency with the theory and not for detailed validation. If the theory survives such a general examination, while its "construct validity" will be enhanced, it will still require refinement and precise validation from further carefully designed experiments.

Before examining the results of specific experiments it is necessary to formulate the general expectations in terms of group differences in "learning efficiency" as measured by such scores as the number of trials required to learn to a criterion. As, in most learning experiments with human subjects, the relevant drive is presumably related to social conformity and achievement, and the placing of the subject in the experimental situation is a form of threat, however mild, it is assumed that avoidance drive will invariably be evoked to some degree and, therefore, the postulated differences in drive arousal will be operative. The relationship between these differences and the degree of stress is expressed graphically in Fig. 13.1.

In considering the consequences of such drive differences, the relationship between strength of drive and efficiency of learning has to be taken into account. Much evidence indicates that, at least for complex learning and avoidance motivation, a very high level of drive decreases efficiency and the overall relationship between these two variables is curvilinear rather than linear. (Courts, 1942; Hebb, 1955; Malmö, 1957.) An excellent empirical example of this relationship is provided by the classic Yerkes-Dodson experiments on discrimination learning in mice and kittens (Yerkes and Dodson, 1908; Dodson, 1915), which are discussed fully in the chapter by P. Broadhurst and which clearly indicate that the optimum intensity of "shock" reinforcement varies inversely with the difficulty of the discrimination task. If this is a principle of general application to learning situations it may be stated in terms of two general laws—

1. "Efficiency of learning is a curvilinear function of drive strength, some intermediate level of drive being optimal."
2. "Optimal drive strength is an inverse function of the difficulty of a learning task."

These laws, which are expressed graphically in Fig. 13.2, are consistent with the major predictions made by the Iowa group (Farber, 1954; Taylor, 1956; Spence, 1956) concerning the relationship between

FIG. 13.1. GROUP DIFFERENCE IN AVOIDANCE DRIVE AROUSAL

drive strength and learning performance on tasks of varying complexity. It is surprising that Spence and his co-workers nowhere consider the Yerkes-Dodson principle though, for their theory to be valid, predictions from it concerning discrimination learning should be consistent with this finding.

Though the Iowa workers recognize the importance of the stimulus aspects of drive (cf. Farber, 1954, 1955) only its energizing effect is considered in their

theory which is based on the Hullian concept of excitatory potential as a multiplicative function of habit and drive strengths. In a situation in which only a single habit is evoked an increase of drive is expected to improve performance but, where competing response tendencies are operative, of which only one is scored correct by the experimenter, the effect of changes in drive strength is considered to depend on the number and comparative strength of the competing

FIG. 13.2. ISOMETRICS OF LEARNING EFFICIENCY ON AN ARBITRARY SCALE OF 1 TO 8 (LOW TO HIGH)

tendencies. When the correct response is based on a relatively weak habit strength, increased drive is deleterious in that the stronger incorrect tendencies gain relatively more in excitatory potential and have, therefore, an enhanced probability of evocation. During learning, as the relative strength of the correct tendency increases, increased drive becomes progressively less injurious and ultimately advantageous when the correct response is pre-potent. In the complex situation, involving competing tendencies, increased drive may also lower efficiency by raising new incorrect competing responses above the threshold value of excitatory potential. This theory is dependent upon the range of oscillation of a response tendency being constant, as Spence (1956) assumes, or, if variable as Hull assumes, being a function of habit strength rather than reaction potential. Hull's statements on this point are unclear and little direct evidence is available. Buchwald and Yamaguchi (1955) submitted the theory to a fairly direct test by training rats in a T maze to a criterion of ten correct responses out of twelve and then with the maze reversed, retraining under low and high drive conditions. Contrary to the prediction derived from the theory, relearning was more rapid with high drive.

According to the algebraic summation theory of discrimination learning (Spence 1937; Jones, 1958b)

the positive and negative responses to the negative (non-reinforced) stimulus compete during learning. The negative (correct) response is initially weaker and only gains minimal ascendancy at the end of training. Thus the Iowa theory would clearly yield the prediction that increased drive should tend to lower the efficiency of discrimination learning at all difficulty levels and throughout the range of drive but this effect should be most marked for difficult discriminations, when the initial ascendancy of the positive (incorrect) response is maximal. This prediction is only in partial accord with the Yerkes-Dodson data and it seems likely that the Iowa theory is not a sufficient explanation of the relationship between drive and performance.

The main alternative hypothesis relevant to this problem has been well described by Child (1954) who takes into consideration the stimulus aspects of drive. Like Mandler and Sarason (1952) he suggests that a heightened drive state is linked with a number of previously learned response tendencies, frequently emotional in nature and irrelevant to the task in hand and which disrupt performance by competing with the correct response. Child suggests that such disruption occurs, owing to increased conflict, only when the task already involves competing tendencies, but the writer agrees with Taylor (1956) that to limit the theory in this manner is merely to complicate the Iowa hypothesis without adding to its predictive value. Nevertheless, there is considerable force in Child's arguments in support of interference, and it is likely that increased drive, particularly of an avoidance nature, is liable to set up task-irrelevant response tendencies. For these to affect scores in experimental situations, however, the irrelevant responses must be incompatible with the experimentally "correct" response and/or be included within the experimenter's scoring system. A muscular tremor may be considered as an example of the expected type of irrelevant response. In simple conditioning this is unlikely to be incompatible with the measured response and may even facilitate it. Only if such C.A.D. mediated responses become so massive as to force themselves on the experimenter's attention are they even recorded. In complex tasks, such as the serial learning of a stylus maze, the correct response is scored, as are certain specific predetermined incorrect responses. A movement determined by the tremor response, when the stylus is at a choice point, will be incompatible with all or all but one of the scored responses and, if randomly determined, will not affect the relative probabilities of these. The effects of a tremor would be to reduce the reliability of an individual's scores and to increase the time taken to traverse the maze. In a task such as target pursuit, any particular tremor response would be incompatible with "keeping

on target" and, as the entire time spent off the target is usually involved in the scoring system, the tremor would materially affect a subject's score. Thus, the effect of task-irrelevant responses depends on their relevance to the scoring system and can only be evaluated when an adequate behavioural analysis of the task can be made.

A further possible effect of changes in drive has been neglected by both these theories. This is concerned with the stimulus properties of drive, as such, and can best be illustrated by reference to discrimination learning. Discrimination is most difficult to achieve when the positive and negative stimuli are most nearly alike, i.e. when they have most elements in common. The incidental experimental stimuli contribute to what they have in common and one of these is the drive stimulus. The stronger the drive, the more intense the drive stimulus, the greater its share of the stimulus complex, the greater the similarity between the positive and negative stimuli and, therefore, the greater the difficulty of discrimination. This effect would be opposed to any energizing value of increased drive and the interaction of the two effects would determine the optimal level of drive, thus producing a pattern of results similar to those reported by Yerkes and Dodson. In simple conditioning, where a single stimulus is linked with a single response, no deleterious effect would result but in trial-and-error learning of all types, discriminations between stimuli are as important as in discrimination learning though the additional factor of response selection is also involved. This hypothesis is akin to that advanced by Hilgard, Jones and Kaplan (1951) concerning the relationship between anxiety and discrimination learning. They suggest that anxious subjects perceive situations as more threatening than do non-anxious subjects and that "a person whose discriminations are dimmed by anxiety" is less likely to differentiate between the positive and negative stimuli.

A fourth possibility is that there exists a stable curvilinear relationship between drive and efficiency with a stable optimum drive value (Hebb, 1955) but that increasing task difficulty, irrespective of the degree and nature of response competition, increases drive in a manner analogous to the drive increment postulated as following frustration (Brown and Farber, 1951; Child and Waterhouse, 1953; Marx, 1956). If so, the optimum pre-task drive level would be lower the more difficult the task. This hypothesis is consistent with empirical studies of the relationship between task difficulty and such measures as muscle tension and palmar skin resistance (cf. Freeman and Giese, 1940) which tend to indicate that task difficulty is a stressor factor increasing drive.

The four hypotheses, outlined above, are not

mutually exclusive and all the postulated effects may contribute to the nature of the interaction between drive and performance. Their relative importance will vary from situation to situation but all are likely to produce the type of relationship reported by Yerkes and Dodson and postulated in the two general laws stated earlier.

In any learning situation an individual's performance will be determined, not only by his level of drive, but also by his position on the personality dimension of introversion-extraversion. The postulated effect of this factor alone is graphically illustrated in Fig. 13.3. but this will interact with the effects of drive according to the nature of the task. Thus, in the formation of a C.A.D. to an originally neutral stimulus, the imbalance towards excitation in introverts and towards inhibition in extraverts should ensure more effective conditioning in the former. The high unconditioned avoidance drive of neurotics, however, would tend to allow them to condition faster than normal subjects. Thus, while it may be predicted that neurotic introverts or dysthymics will condition most readily and stable extraverts least, no firm prediction can be made as to the comparative conditionability of stable introverts and neurotic extraverts (hysteries) unless the degree of stress is determined. As drive differences increase with degree of stress (Fig. 13.1.), while the difference between

FIG. 13.3. LEARNING EFFICIENCY AS A FUNCTION OF INTROVERSION-EXTRAVERSION

excitatory and inhibitory potentials remains constant, stable introverts will be expected to condition faster than hysterics at low strength of the conditioned stimulus but at high stimulus strengths, the reverse would hold true. These expectations are graphically represented in Fig. 13.4.

The effects of introversion-extraversion on the growth of conditioned inhibition and, hence, on efficiency of discrimination, are more difficult to

predict. Eysenck (1956b) assumes that the development of conditioned inhibition, being a learning process, is slow in extraverts. As, however, the learning involved is the learning of a response of "not responding" and the postulated relevant drive is reactive inhibition, conditioned inhibition may well develop more readily in extraverts. For trial-and-error and other complex situations the interaction between drive and inhibitory effects is inevitably

FIG. 13.4

(For full explanation, see text)

complicated. At low levels of stress, when drive is below the optimum for all groups, dysthymics should be most efficient and stable extraverts least efficient, as in conditioning, but no firm prediction can be made of the relative efficiency of stable introverts and hysterics. At high levels of stress, when drive is above the optimum for all groups, both stable groups should be superior to both neurotic groups, with the introverted subjects superior within each category. In the intermediate range of stress, however, when drive is approximately optimal for one or other group, prediction of empirical results is virtually impossible. The intricacy of these interactions is illustrated in Fig. 13.5. which represents one of the possible sets of relationships consistent with our hypothesis. The interactions are further complicated when the stress involved in the task is not the result of the direct application of some unconditioned avoidance stimulus but results from some C.A.D. evoked by intrinsically non-traumatic stimuli in the situation. The conditionability differences shown in Fig. 13.4. then come into operation and the curves of Fig. 13.5. become distorted into those of Fig. 13.6. with the effect that their intercrossings in the range of moderate stress are further complicated and the extraverts are now superior to introverts at very high levels of stress.

From the Iowa hypothesis concerning the effects of intra-task response competition and the later hypothesis concerning the effect of task difficulty, increased response competition or increased task difficulty will have the same effect on group differences in learning efficiency as increased stress. Thus the abscissae of Figs. 13.5 and 13.6 represent both stress and task difficulty or some joint function of these.

Individual Differences: Review of Empirical Data

The review which follows is not intended to be exhaustive. Apart from such factors as availability,

devised to test the Iowa hypothesis, described above, and it is assumed that M.A.S. scores are positively related to drive level and, according to Taylor (1956), any other specification of drive, e.g. hunger, would have been equally acceptable as an independent variable for their experiments. As both Taylor and Farber (1954) admit, anxious and non-anxious subjects differ in respects other than drive and these other differences are likely to influence performance but the Iowa researchers have deliberately neglected such additional factors. This standpoint would be defensible if the non-drive factors contributing to the

FIG. 13.5

FIG. 13.6

(For full explanation, see text)

language and recency, studies have been selected in terms of the ease with which their results can be examined for compatability with the type of generalization concerning group or individual differences made in the preceding section. Only those studies which present data concerning learning, in the sense of improvement with practice, have been included; reports concerned with immediate memory have been omitted. Though greater weight must be attached to trends of demonstrable statistical significance, data exhibiting trends at an insignificant level are included. This is considered justifiable as an insignificant trend, if repeatedly observed, gains inductive power. It is hoped that no study has been omitted, the results of which run clearly counter to the theoretical biases which are no doubt evident throughout this chapter.

Ideally, the empirical evidence to be matched against our theoretical expectations should be derived from investigations employing neurotic subjects. Unfortunately, however, the majority of studies concerned with the psychodynamics of learning have utilized normal subjects. These are valuable and relevant to abnormal psychology when the personality variables taken into account are ones for which extreme values are characteristic of psychiatric patients. This is true of the many recent studies employing the Taylor Scale of Manifest Anxiety, or M.A.S., (Taylor, 1953). This scale was specifically

variance of M.A.S. scores were uncorrelated with the drive factor itself, which is unlikely. The M.A.S. has been discussed at length in the preceding chapter. In terms of Eysenck's dimensional system, it can be considered as largely a test of neuroticism and thus, in view of the theoretical interpretation of that factor, as mainly a measure of drive level. However, it is also likely to have a smaller but appreciable projection on the factors of introversion-extraversion. Furthermore, it is a scale of *manifest* or response-defined anxiety and therefore, indicative of habitual responses to stress. Finally, the stimulus aspects of anxiety may be of importance in the manner described above. Thus, an individual obtaining a high M.A.S. score is likely to have his learning performance enhanced by virtue of his relatively high excitatory potential and interfered with by habitual anxiety responses and impaired discriminations quite apart from the specific energizing effects of drive level, which may become masked or distorted.

Spence (1956) assumes, like Hull, that any drive present, whether relevant or not to the task in hand, will contribute to a "total effective drive state." This is acceptable in that it is one of the notions, whose implications are being tested in the researches. More difficult is the question whether an individual, scoring high on the M.A.S. and, presumably, having a history of manifestly anxious responses in a variety of circumstances, has a chronically high level of emotional

arousal or whether the experimental situation has to be moderately novel, threatening or otherwise stressful in order to allow individual differences in emotional reactivity to become effective. Taylor (1956), reviewing evidence on this point, concludes that such individual differences are operative in most testing situations but that situational stress enhances their effects though not necessarily only by increasing differences in drive level. This problem is equally applicable to the individual differences in drive postulated as underlying the neuroticism dimension and Taylor's conclusion was implicitly assumed in the earlier theoretical discussion.

Most of the Iowa Studies and others making use of the Taylor scale employed groups of subjects, usually undergraduates, characterized by extreme M.A.S. scores and described as anxious or non-anxious. For experiments on differential conditioning, Spence and his co-workers (Spence and Farber, 1954; Spence and Beecroft, 1954) predict that anxious subjects compared with non-anxious will show greater excitatory strengths in response to the positive stimulus and to the negative stimulus and a greater difference in excitatory strengths. These predictions follow from their drive theory but, if the stimulus aspects as described earlier, are also considered, prediction becomes difficult in that the stimulus effects would tend to increase to a greater degree the excitatory strength to the negative stimulus for the anxious subjects and, therefore, tend to reduce their difference score. The overall effect on the difference would depend on the difficulty of the discrimination, i.e. the degree of similarity between the two stimuli. Spence and Farber explicitly assume that the internal drive stimuli have, for their groups, equal and relatively negligible habit loadings.

The authors' predictions were significantly confirmed for the responses to the positive stimulus, for four of five separate experiments, and they were generally supported by insignificant trends for the responses to the negative stimulus and the difference scores. This difference in predictive accuracy is consistent with the postulated stimulus effect. No predictions were made for the overall efficiency of discrimination learning but Restle and Beecroft (1955) reanalysed these data in terms of discrimination indices and found no differences between the subject groups.

In marked contrast to these findings are those of Hilgard, Jones and Kaplan (1951) who found that anxious subjects made an insignificantly greater number of responses to the positive stimulus than did non-anxious subjects but a similar difference was significant for the negative stimulus. This finding is contrary to Spence's predictions: for both groups of results to be consistent with the two-factor theory the

positive and negative stimuli should be more alike in the earlier study than in the Iowa experiments. In fact, different modes of stimulation and different dimensions of generalization were employed: whereas the Iowa workers used a 500-cycle tone as the positive stimulus and a 5,000-cycle tone as the negative stimulus, Hilgard *et al.* used equally illuminated windows to the right (positive) or left (negative) of a central fixation point.

Later investigations, while tending to support the two-factor theory, fail to settle the issue. This would require a repetition of the Iowa type of experiment but with experimental variation of the "distance" between positive and negative stimuli. Stevenson and Iscoe (1956) performed a discriminative learning experiment, using three squares of differing area and anxious and non-anxious subjects. The latter were significantly superior in learning and less variable. Bendig and Vaughan (1957) replicated this experiment but failed to cross-validate the finding at a significant level. Kamin (1955) found M.A.S. scores to be significantly and negatively correlated with the number of false responses to the negative stimulus in a discrimination situation but this finding failed to survive cross-validation and the original correlation lost significance when scores on a mechanical aptitude test were held constant. In a further experiment (in which mechanical aptitude was not measured) Kamin *et al.* (1955) report a similar correlation both with M.A.S. scores and intolerance of painful stimulation. The latter two measures were, however, uncorrelated and, as the pain tolerance scores were related to response latencies whereas M.A.S. scores were not, the authors suggest that high anxiety scores are related to impaired discrimination in this situation but low pain tolerance scores imply heightened avoidance tendencies producing higher probabilities and shorter latencies of response. The latter hypothesis implies a correlation between pain-intolerance and the number of correct positive responses but these data are not reported.

Stimulus generalization is theoretically akin to differential conditioning and the effect of increased drive, by virtue of both its energizing and stimulus properties, would be to increase responsiveness to generalized stimuli. Spence and Beecroft, in the paper already cited, report an insignificant trend in the reverse direction but Rosenbaum (1956), employing visual figures of differing height and a motor response, found that anxious, when compared with non-anxious subjects, showed significantly more generalization. This group difference was enlarged significantly when the subjects were given strong intermittent shocks during their performance of the task but not when weak shock or a buzzer was used. Wenar (1954) in a somewhat similar experiment, but testing temporal generalization, found that reaction-time tended

(insignificantly) to be a function of both stimulus intensity (buzzer—weak shock—strong shock) and M.A.S. scores but there was no evidence of an interaction between these factors. Lacey, Smith and Green (1955) established conditioned cardiac responses to the word *cow* and report that subjects with high scores on a version of the M.A.S. show increased generalization to other words of rural connotation. This trend was consistent but insignificant. Farber and Spence (1956) failed to demonstrate any significant relationship between anxiety and generalization as measured by reaction-time but point out that the same is true of all investigations into generalization and discrimination when the criterion measure is response latency.

Serial learning tasks were employed by Taylor and Spence (1952) and Farber and Spence (1953) to test their theory concerning the effects of changes in drive on competing response tendencies. In the earlier study the task was a form of serial verbal "maze" and in the other a stylus maze. Assuming that errors on these tasks result from interference from response tendencies derived from remote associations, the authors predicted that anxious subjects would make more errors and take more trials to learn to a criterion than would non-anxious subjects. These predictions were confirmed at a significant level and, in an independent study by Matarazzo *et al.* (1955), a significant positive correlation was established between the number of trials to learn to a criterion on a stylus maze task and the full range of M.A.S. scores. In both Iowa studies, in accordance with a further prediction, a significant rank-order correlation was demonstrated between choice-point difficulty and differences in errors between the anxious and non-anxious groups. Even at the easiest choice-points, however, where errors were very few, the anxious subjects tended to be inferior whereas the reverse would be expected from the Iowa hypothesis. This is consistent with expectations derived from Fig. 13.5. provided that the overall difficulty-stress ratings of the tasks locate them to the right of centre along the abscissa. The validity of the finding has, however, been questioned by Axelrod, Cowen and Heilizer (1956) and, for the stylus maze task, when subgroups of anxious and non-anxious subjects were matched for total score, the anxious subjects were significantly superior at the easiest choice points and inferior at the most difficult. Axelrod *et al.* reanalysed the Farber and Spence data, allowing for overall differences in performance, and found the resulting correlation to be negative but insignificant. They also carried out a replication of the maze study but included subjects with middle-range M.A.S. scores. Though no significant differences were established in terms of errors, trials to criterion, or differential performance at choice-points of varying

difficulty, all trends were in the direction predicted on the basis of the Iowa hypothesis. Of considerable interest is these authors' finding that the "lie" scale of the M.M.P.I. (Hathaway and McKinley, 1943) was related more closely to learning performance than was the M.A.S.

Hughes, Sprague and Bendig (1954) failed to establish significant differences between groups with extreme M.A.S. scores on several serial verbal mazes as used by Taylor and Spence. They presented the stimuli, however, at intervals of four seconds whereas the former study had employed a two-second rate. Thus their tasks would be less stressful and located further to the left in Fig. 13.5. In these studies, consistent but non-significant negative correlations were found between choice-point difficulty and differential group performance as calculated in the Iowa studies.

Montague (1953) varied systematically the amount of interference in serial verbal learning by constructing three series of nonsense syllables with different extents of intra-list similarity and different association values. He reports a significant interaction between M.A.S. scores and interference values, anxious subjects being superior for the list with high association values and low intra-list similarity while non-anxious subjects were superior for the list of low association values and high similarity: difficulty level, as such, was uncontrolled in this experiment. Data most damaging to the Iowa hypothesis were obtained by Saltz and Hoehn (1957) in an investigation similar to Montague's but in which, by manipulation of the factors of intra-list similarity and association value, the authors selected "competing" and "non-competing" serial nonsense syllable lists which were empirically shown to be of equal difficulty for a group of non-anxious subjects. The performance of anxious subjects was very similar for both lists and the absolute difference was in the direction opposite to prediction. In a second experiment the performance of anxious and non-anxious groups was compared for easy-competing and difficult-non-competing material. Contrary to prediction there was no significant difference at the former task but the anxious group was significantly inferior at the difficult non-competing task. The authors conclude that M.A.S. scores are related to difficulty level rather than response competition and suggest that greater difficulty imposes greater stress and, therefore, releases potential anxiety. This view is consistent with our fourth drive-efficiency hypothesis.

Sarason (1956) found, under neutral conditions, that high scorers on the M.A.S. were superior to middle and low-anxious groups in the serial learning of nonsense syllables of high associative value but, with ego-oriented instructions to the effect that the task was a form of intelligence test, the latter two

groups improved in performance whereas the high-anxious subjects deteriorated significantly. The effect of these instructions remained significant twenty-four hours later. Stress was further varied by making failure or non-failure reports on the subject's performance. Failure information resulted in lowered performance for all groups but this effect did not persist over twenty-four hours and affected all groups equally. In a later paper (Sarason, 1957a) a replication study is described using syllables of slightly lower association values (53 per cent), ego-oriented instructions as before, task-oriented motivating instructions and neutral control instructions. The results in general were consistent with those in the previous study with the task-oriented instructions being insignificantly less effective than the ego-oriented condition. In this study there is some evidence that low-anxious subjects responded differently from the middle-anxious group and in the same direction as the high-anxious group. Failure motivation was investigated further in a third study (Sarason, 1957b) employing high-and low-anxious groups. One group of each type was failed on a preliminary list of nonsense syllables similar to the experimental task. Other equivalent groups were failed on a dissimilar digit-cancellation task. Control groups, receiving no failure reports, showed no difference in performance but the low-anxious subjects were superior after both types of failure stimulation. Anxious subjects showed similar impairment of performance from both failure conditions but, whereas non-anxious subjects failed on the syllable task were no different from the non-anxious control group, the non-anxious group failed on the cancellation task were significantly superior to all other groups. As the experimental design ensured that the cancellation task was closest in time to the experimental task, this is consistent with Doris and Sarason's (1955) finding, for a non-learning task, that the nature of the interaction between anxiety and failure depends on the order of the tasks failed but is also consistent with more extensive generalization of failure effects for anxious subjects. The general pattern of all Sarason's results is consistent with our theoretical expectations but his detailed findings illustrate the complexity of the possible interactions of effects.

Beam (1955) investigated the interrelationships between serial nonsense-syllable learning, M.A.S. scores and stress, ingeniously induced by taking advantage of real-life stress situations. The scores of fifty-four subjects just prior to a doctoral examination, making an important oral report, or the "first night" of a dramatic performance were compared with those achieved in neutral conditions. On each occasion palmar sweat indices were recorded. The results indicate that stress had a highly significant and deleterious effect on learning efficiency, the magnitude of

which has correlated with increases in the amount of palmar sweating. M.A.S. scores, however, were not related to either effect. While stress impaired complex learning, G.S.R. conditioning was facilitated.

Silverman and Blitz (1956) threatened anxious and non-anxious groups with shock in two ways. Half the subjects were told, "You *may* receive a shock" and half, "You *will* receive a shock." The former instruction was considered an avoidance situation in that it implied that good performance would prevent shock and, consistent with this interpretation, non-anxious subjects decreased their errors on a serial rote-learning task in the avoidance situation and increased them in the non-avoidance situation. The anxious group slightly improved their scores in both conditions. There were no significant differences between anxious and non-anxious groups during preliminary training but on a test of the incidental learning of digits, the anxious group, presented with words to be learned, was significantly inferior. The experimental conditions had no effect on incidental learning. These results are clearly opposed to our theoretical expectations as no variants of Figs. 13.5 and 13.6 would portray declining normal performance through a range of stress within which neurotic performance improves. Hypotheses concerning failure, by the anxious subjects, to discriminate between the implications of the two forms of instruction might account for the differences but these would be very much *ad hoc*.

The results of Deese, Lazarus and Keenan (1953), obtained in a rather similar experiment are equally difficult to explain. Anxious and non-anxious subjects were divided into three groups, one receiving intermittent shocks, one receiving shocks when responding incorrectly and one under neutral conditions, while they were learning serial nonsense syllables of minimal similarity. For the combined conditions the anxious subjects were significantly superior but there was a significant interaction between anxiety and conditions to such an extent that the largest group difference occurred in the avoidance situation, owing to facilitation of performance in the anxious group and a decrement in the performance of the non-anxious group. Under the intermittent shock conditions, the group difference results entirely from deterioration of the performance of non-anxious subjects. The authors quote evidence to indicate that M.A.S. scores are related to the hysteria-psychasthenia continuum. This is in accord with the suggestion, made earlier, that the M.A.S. is related to introversion-extraversion as well as to neuroticism but Deese and his co-workers suggest that both extremes of M.A.S. scores reflect neurotic tendencies and anxiety but that low scorers have erected strong hysterical defences against their anxiety which break down under

objective inescapable stress such as shock. The high scorers or psychasthenic (dysthymic) individuals, while generally displaying their anxiety, react to objective stress in a cool and intellectual manner. A hypothesis of this type would also account for Silverman and Blitz's results if threat of shock can be equated with shock, and would render both sets of results compatible with theoretical expectations. Lazarus, Deese and Hamilton (1954) report a further analogous experiment but using a more difficult list with high intra-list similarity. No significant differences were observed between the groups, nor between the stress-no-stress conditions but Taylor (1956) points out that all groups only averaged about one correct response per trial and, hence, the difficulty of establishing group differences in learning.

Consistently with Deese's interpretation of the M.A.S., Matarazzo, Ulett and Saslow (1955), when considering the total time taken to solve their maze, found a significant but curvilinear relationship with anxiety scores such that scorers in the mid-range were superior to both high and low scorers, but this is equally consistent with the curves of Figs. 13.5 and 13.6. It has been argued earlier that irrelevant competing responses are unlikely to affect error scores in a maze-learning situation but might well affect speed of performance. In conjunction with Matarazzo's *et al.* findings, this would suggest that both high and low M.A.S. scores are likely to be indicative of interference tendencies. Matarazzo *et al.* (1954) found a similar curvilinear relationship between M.A.S. scores and timed tests of intelligence, as did Siegman (1956), but no relationship with untimed intelligence tests but this was not confirmed in a later study (Matarazzo and Matarazzo, 1956). Discussing these findings, Matarazzo (1955) stresses the high negative correlation between the M.A.S. and the validity scale K of the M.M.P.I., which he interprets as a "defensiveness" scale.

Paired-associate techniques have been employed in several of the Iowa studies (Ramond, 1953; Taylor and Chapman, 1955; Spence, Farber and McFann, 1956; Spence, Taylor and Ketchel, 1956; Spence, 1956). Consistently, the performance of anxious subjects was superior for adjective pairs of high initial S-R associative strengths and minimal inter-pair similarity but non-anxious subjects were superior when stimulus members were similar or synonymous. In one experiment, the predicted superiority of anxious subjects was evident with an anticipation interval of 2.2 sec but disappeared with an interval of only 1.1 sec, which made "the learning problem . . . very difficult and quite stressful." This result is consistent with a move to the right along the abscissa of Fig. 13.5 and is used by Spence as evidence for task-interfering responses counteracting the greater

energizing value of the high drive of anxious subjects.

Ramond's study is of particular interest. Each stimulus adjective was presented with a pair of response words, one of initially high and one of initially low associative linkage with the stimulus, from which the subject had to select the correct response e.g. tranquil < serene (✓) / rugged (×).

Elsewhere in the series a synonymous stimulus word was presented with the same response words but with the previously incorrect response now correct e.g. peaceful < serene (×) / rugged (✓).

As expected, non-anxious subjects were superior when the responses of low association value were correct. No significant difference was observed between groups when the high association responses were correct though there was a tendency for anxious subjects to be superior early in learning and inferior later. Though insignificant in extent, this trend was almost exactly duplicated in two of the later studies and is interpreted as resulting from growing interference, by generalization, from the gradually learned weak response. Though consistent with the Iowa hypothesis, in view of Saltz and Hoehn's results with serial learning, these results are ambiguous without adequate control of the difficulty factor.

Gordon and Berlyne (1954) introduced additional stress into a paired-associate task by informing the subjects that the task was a test of intelligence. Anxious subjects then tended, insignificantly, to require more trials to learn to a criterion. Half the subjects in each group were then told that their performance was above average and half that their performance was below average. Success information failed to produce differences in the performance of anxious and non-anxious groups in a second task but, with failure information, the anxious subjects were significantly inferior, though all groups took less trials to learn the second list than to learn the first.

Korchin and Levine (1957) varied difficulty and stress for two groups of normal subjects, anxious and non-anxious in terms of M.A.S. scores, and a group of hospitalized psychiatric patients with anxiety symptoms. All groups learned paired-associate tasks of two types, simple logically related word-pairs and incorrect multiplication formulae. Half the subjects in each group were tested with immediate (high stress) and half with delayed (low stress) inter-trial spacing. The non-anxious normal subjects were significantly superior to the anxious normal subjects for the false equations and a similar but insignificant difference was observed for the word-pairs: the different spacings had no effect on these trends. The patients were approximately equal in efficiency to the anxious normal subjects with delayed spacing but deteriorated

with immediate spacing on both tasks. Both the high anxiety and patient groups tended to make more failures of response (no response rather than a false response) with immediate spacing.

Westrope (1953) tested anxious and non-anxious groups on a lengthened version of the Wechsler-Bellevue Digit Symbol test over eighteen trials in blocks of seven, five, three and three. Her results are represented graphically in Fig. 13.7 and display a consistent trend for the anxious to be superior to the non-anxious subjects over the first fifteen trials when conditions were neutral. The last three trials were administered in highly stressful conditions including observation, signals of "unsatisfactory" performance and impending shock, and actual shock. Performance declined during the stress period and the curves show a tendency for the non-anxious subjects to be superior to the anxious. The overall effect of stress was statistically significant while the interaction between anxiety and stress approached significance.

Fig. 13.7 clearly shows that in this study, as in others, though stress may effect learning, as such, its main effect is on performance, which falls well below the level already achieved. Carlson and Lazarus (1953), in a similar study, found that the slope of the improvement curve under stress was significantly and positively correlated with subject's scores on Winne's neuroticism scale, a measure highly correlated with the M.A.S.

Davidson, Andrews and Ross (1956) investigated the effects of anxiety and various types of stress on a continuous colour-naming task. They found no significant effect for the M.A.S. scores alone but various significant interactions between anxiety and stress. This suggests that M.A.S. scores indicate increased susceptibility to stress rather than chronic anxiety. In accordance with this notion, anxiety scores correlated positively with subjective experience of stress as reported on a questionnaire following the experiment.

Grice (1955) set a complex discrimination reaction-time task to two groups of airmen trainees, representing both extremes of M.A.S. scores. For both reaction-time and error scores the low-anxious group was significantly superior and showed significantly greater superiority on tasks of greater difficulty but, when analysis-of-covariance techniques were applied, it was shown that these differences could be accounted for in terms of general intellectual ability. This finding casts some doubt on the validity of other studies employing the M.A.S. but which do not control for intellectual factors. The correlations, however, between M.A.S. scores and most tests of intelligence are negligible (Taylor, 1955; Mayzner *et al.*, 1955), at least for groups of students and, as Grice points out, the range of intelligence in his group is considerably wider than in most other studies.

Matarazzo and Matarazzo (1956), with the above result in mind, carefully controlled age, education and intelligence in an investigation into the relationship between M.A.S. scores and performance on a complex, double disc pursuitmeter, using as subjects psychiatric and non-psychiatric hospital in-patients. These authors failed to establish any significant relationship between performance and anxiety but report a trend for subjects with middle-range M.A.S.

FIG. 13.7. DIGIT SYMBOL LEARNING OF "ANXIOUS" AND "NON-ANXIOUS" SUBJECTS IN STRESS AND NON-STRESS CONDITIONS

Data for both sexes combined.
(After Westrope, 1953)

scores to benefit most from practice. Maltzmann, Smith and Brooks (1956) found that subjects making relatively high numbers of target hits in a target-tracking task had significantly lower anxiety scores than those making relatively few hits.

Apart from the studies by Silverman and Blitz and by Deese, Lazarus and Keenan, all the studies reviewed, employing Taylor's scale, are consistent with the general expectation described in the earlier theoretical section. Two distinct possibilities emerge which merit further investigation: task difficulty, empirically determined, may be more important than the factors of response competition stressed by the Iowa group and many of the relationships between M.A.S. scores and other variables may be curvilinear rather than linear in nature.

Mandler and Sarason (1952) have employed a different type of anxiety questionnaire, intended to be a measure of "test anxiety," the anxiety evoked by such situations as formal examinations and psychological tests of ability. They make a formal statement of their hypothesis that subjects, scoring high on their questionnaire, respond to such tasks, not only with increased drive, but also with previously learned task-irrelevant responses to their anxiety, which

interfere with performance. Predictions, derived from this hypothesis, are made concerning the results of an experiment involving repeated testing with items of Koh's Block Design Test and versions of the Wechsler Digit Symbol Test. Though these are essentially tests of intelligence, their repeated application produced typical learning curves. Scoring was mainly in terms of speed of performance and, as argued earlier, should therefore be affected by test-irrelevant responses. Stress was experimentally varied by success, neutral or failure reports to the subjects at the half-way stage. As predicted, during the non-stress period, anxious subjects tended to be inferior but not always to a significant degree. As Child (1954) points out, their interpretation of these results is equivocal owing to the specific nature of the anxiety measured, which could derive from, as well as bring about, the performance differences. This criticism is not, however, applicable to the predictions made concerning variability differences between the groups, which were confirmed at a significant level. Under stress, the anxious subjects were expected to deteriorate, owing to interfering tendencies, while the non-anxious subjects were expected to improve, owing to increased drive. Appropriate results were obtained for the Koh's Designs but no significant effects were observed on the Digit Symbol test. Success stimulation tended to produce effects similar to failure stimulation though to a lesser and insignificant degree.

Sarason, Mandler and Craighill (1952) made a similar digit symbol task sufficiently long to ensure that no subject could complete it in any one trial. Stress was varied by telling subjects that they either should or should not be able to finish in the time allowed. As predicted, anxious subjects were inferior but significantly so only for the stress condition. No absolute differences in variance were observed but the predicted trends of change in variance approached significance. Stress, as expected, improved the performance of non-anxious subjects but had no apparent effect on the anxious group. Child (1954) points out that these effects were of similar magnitude on the first and subsequent trials, when the subjects were aware that they would not complete the task. In the same paper, a second experiment is described in which ego-oriented or task-oriented instructions were given before performance on a stylus maze task, scored both in terms of errors and time. The results tended to fall in the predicted directions but most trends failed to achieve statistical significance.

In support of their view that test-anxious subjects, with repeated rewarded practice, should learn to modify their habitual responses to anxiety arousal so as to make them task-relevant and non-interfering, Sarason and Mandler (1952) report that individuals

scoring high on their questionnaire have relatively low scores on aptitude tests at the beginning of a college course but show slight relative superiority in terms of their later average college grades. As, presumably, the anxiety questionnaire was administered subsequently to the achievement of the relatively high grade averages, this finding cannot be explained in terms of the extinction of the anxiety response. In a further study, Mandler and Sarason (1953) show that test-anxious subjects tend, more than non-anxious subjects, to rate their performance as inferior. This subjective experience is an important factor in the performance of these subjects but its effect can be counteracted by specific success reports. Altogether, these investigations present strong evidence in support of the hypothesis of interference from task-irrelevant responses. The scores taken are, in general, such as would reflect such interference and the trends observed are consistent with the relationships portrayed in Fig. 13.5, provided that the stresses involved were only moderate, as seems likely.

A third personality questionnaire, the Interference Tendency Questionnaire (I.T.Q.) was employed by Waterhouse and Child (1953). This samples an individual's characteristic responses to frustration with particular reference to tendencies to respond in a manner likely to interfere with adequate performance of a task. Sarason and Mandler (1953) report a correlation of 0.47 between this measure and their own test-anxiety scale. Waterhouse and Child, and Williams (1955), demonstrated interrelationships between scores on this scale, motivating conditions, and performance on a wide variety of tasks very similar to those established in the investigations of Mandler and his associates. Except in two instances, however, these tasks were scored in terms of absolute score not in terms of learning and were, frequently, of an intellectual nature. It is of interest, however, that in most instances the scores taken were essentially speed scores.

Indices derived from the Rorschach test were used by Williams (1947) as measures of emotional and intellectual control and were shown to correlate highly with deterioration of performance on a digit symbol task under a combination of stresses such as shock, threat of failure and observation. Not surprisingly, in view of the general lack of validity of the Rorschach technique (Payne, 1955), this finding was not confirmed in a replication study by Carlson and Lazarus (1953) who also cite studies by Allee and by Stopol which also failed to relate performance under stress to Rorschach measures. Westrope (1953) also included Rorschach indices in the study described earlier but none of these were predictive of stress effects in the digit symbol task. The group Rorschach technique fared better in an investigation by Ausubel

et al. (1953) into the mirror-drawing and blindfold stylus maze performance of two groups of subjects selected as scoring in the upper or lower fifths of a distribution of anxiety scores derived from this test. The groups also differed significantly in their responses to an anxiety inventory and evidence of the higher motivation of the anxious group was drawn from level of aspiration scores.

The main evidence concerning the learning ability of these groups derives from the maze task which was repeated over ten trials. At the first trial, the anxious subjects were significantly inferior both in terms of speed and errors. Their slower speed may be due to interference from competing responses but the initial difference in error scores is difficult to explain as, during the first trial, a subject has no basis, apart from chance trial and error, for choosing alleys and experience with early choice-points is no guide to later choices. During the course of the ten trials the anxious subjects increased their speed relatively more and were as fast as the non-anxious subjects on the tenth trial. They also gained more from practice on a simple trial maze and improved more in terms of error scores though this latter trend may well lose significance if the dubious difference in initial error scores is eliminated. When the task is relatively simple, requiring some fifteen to twenty trials for perfect performance, and the stressor elements in the situation are only moderate, the whole pattern of results is such as would be expected from placement of the task in a fairly central position along the abscissa of Fig. 13.5 with, possibly, increased stress during the early stages owing to the novelty of the situation.

Other investigators have employed no psychometric devices but have studied the effects on performance of anxiety induced experimentally in a variety of ways, many of which figured as supplementary variables in the studies already reviewed. Thus, McClelland and Apicella (1947) subjected two groups to failure stimulation and one to success stimulation (described as "neutral" by the authors) while learning a card-sorting task to a criterion. The success and one failure group then "rested" for four minutes, during which they practised a pursuit-meter task with success stimulation, and then completed ten further trials at the card-sorting task with no incentives. The remaining "failure" group proceeded to these additional trials immediately following their initial practice. Both failure groups were significantly impaired in their original learning. In the first of the final ten trials the rested failure group was superior to the rested success group and equal to the non-rested failure group. Thereafter, the non-rested failure group deteriorated whereas the other two groups improved slightly. The authors postulate that failure produced response conflict which lowered performance below

the true level of learning. As failure and success groups were taken to the same performance criterion the failure groups actually learned more and this superiority became evident when the conflicts were removed by the rest period. The failure of the rested failure group to show reminiscence was explained in terms of retroactive inhibition produced by the interpolated task.

Bayton and Conley (1957) varied success and failure at a task requiring manual dexterity by level of aspiration techniques. Learning was measured in terms of speed scores. The experimental subjects were divided into three groups receiving five, ten or fifteen successful trials before experiencing failure. The shift to failure improved performance for the last two groups, but not for the group receiving only five success trials. Thus the effect of failure stimulation is partly governed by the background of reinforcement.

Sarason and Sarason (1957) gave fifteen trials at learning a serial nonsense-syllable list to subjects, half of whom then received ego-oriented instructions and half task-oriented instructions before fourteen trials on a second and equivalent list. Half of each group received failure stimulation and half was engaged in neutral conversation before proceeding with the fifteenth trial of the second list. Twenty-four hours later all groups carried out five more trials with the second list. The groups were compared by analysis of covariance techniques in terms of their performance on trials 15, 16, and 20 of the experimental list. Ego-oriented subjects were superior to task-oriented subjects on trial 16 and failed subjects were inferior to non-failed subjects on trial 15. There was also an insignificant trend for failure to have a greater detrimental effect in the task-oriented group. Thus failure appeared to have an immediate but temporary effect whereas high motivation from instructions had no immediate effect but facilitated later performance. From this and the preceding studies it is clear that the effectiveness of failure motivation depends on many factors but when effective it operates in a manner consistent with theoretical expectation.

Jones (1954), set his subjects a temporal maze task and varied stress in the form of frustration induced by varying fore-periods during which the maze was insoluble. Motivation was varied by giving ego-oriented or task-oriented instructions. His results indicate that short periods of frustration resulted in impaired learning efficiency and increased stereotypy of response but prolonged frustration did not increase this tendency. Ego-oriented instructions consistently exaggerated the effects of frustration but never to a significant degree.

Castaneda and Palermo (1955) tested the implications of the Iowa theory by varying habit strengths; this was done by varying periods of practice at a

paired-associate task with five coloured lights as stimuli and five buttons as response manipulanda. The lists were relearned with three of the stimuli and response elements re-paired and, at this stage, stress in the form of speed instructions was introduced for half the subjects. The results, though trends were not always significant, were confirmatory of the predictions that performance would be impaired by stress when the dominant habit was incorrect, facilitated by stress when the dominant habit was correct and the trends would be magnified with increasing strength of the dominant habit. Castaneda (1956) reports similar findings from an analogous experiment. Though supporting the Iowa hypothesis these results may well derive from difficulty rather than competition factors.

Silverman (1954) investigated the effects of threats of shock (unfulfilled after one demonstration shock) and auditory distraction on performance at a visual size-discrimination task. Both independent variables slightly, but insignificantly, improved performance whereas the combined stresses significantly impaired discrimination. As the task was learned to a criterion by all subjects, before the introduction of the experimental variables, this effect is not one on discrimination learning as such but may reflect changes in the stimulus generalization gradients consistent with the expectations described earlier. Rosenbaum (1953), as in the study previously described (Rosenbaum, 1956), demonstrated flattened generalization gradients with the administration of intermittent strong shock.

Eriksen and Wechsler (1955) studied the effects of random electric shocks on discriminative accuracy, which was tested by recording subjects' absolute judgements of size for a series of eleven squares of different sizes extending over a range within which control subjects had been shown to be capable of absolutely discriminating some four stimuli. When presented with a stimulus square, subjects responded with the number, from one to eleven, corresponding to their judgement. From an analysis of the results in terms of information theory it was concluded that there were no differences in accuracy of discrimination between the experimental and control groups but the stressed subjects were more biased in their use of the eleven categories and more stereotyped in their responses to specific squares. The authors, therefore, suggest that the effects of anxiety on discrimination result from changes in response thresholds rather than from any impairment of sensory discrimination. These findings do not constitute evidence against our hypothesis concerning the effects of a drive stimulus on discrimination learning which refers to response tendencies rather than sensory discrimination. Eriksen and Wechsler's ingenious experiment could well be adapted to form a direct test of this hypothesis but

doubt must be cast on the validity of this method of determining sensory discrimination, which depends on relationships within the response categories used by the subjects. In a somewhat similar experiment, but using a pseudo-E.S.P. situation, instead of absolute judgements, in order to free responses "from external stimulus determination," Kuethe and Eriksen (1957) demonstrated a significant relationship between anxiety on the one hand and stereotypy and bias in selecting numbers from one to eleven on the other. Yet in the earlier experiment category choices were the criteria of sensory discrimination.

Cowen, Heilizer and Axelrod (1955) controlled anxiety or emotional disturbance by selecting, for each subject, six adjectives considered to be related to personal conflicts by virtue of a large discrepancy between the subject's "actual" and "ideal" self-ratings on the traits described by these adjectives. These and six "neutral" adjectives, for which no such discrepancy was noted, were paired with nonsense syllables of low association value and formed a verbal learning task. The neutral pairs were learned significantly sooner than the conflict-related pairs and there was a significant positive correlation between the mean discrepancy score for a given adjective and the trials required to learn the pair in which that adjective figured. The same authors (Heilizer *et al.*, 1956) later reported that there were no significant differences among groups, selected by M.A.S. scores, for the learning of the series as a whole or for the differential learning of conflict and non-conflict word pairs.

Jacobs (1955) found a similar significant tendency for words, considered, by virtue of long reaction-time in a free-association test, to be emotionally significant to a subject, to be learned less readily than neutral words when used as responses to nonsense syllables in a paired-associate list. This was accentuated when the words occurred in difficult serial learning positions. There was also some evidence that these trends were magnified for subjects considered maladjusted. Failure reports, however, tended to neutralize these effects. Merrill (1954) in an analogous experiment also found that "emotional" words were learned less easily by control subjects who showed no associative disturbances to any of the experimental words. An interpolated task, considered to be evocative of anxiety owing to its difficulty, and failure reports reduced efficiency of recall in both groups of subjects.

The Maudsley studies have, to date, been mainly concerned with the dimension of introversion-extraversion though the experimental results are inevitably related to neuroticism as well. The bulk of the work on learning, as distinct from conditioning, has been concerned with rotary pursuit tasks. Eysenck (1956b) reports on an experiment with fifty male students as subjects and which involved three

five-minute "massed practice" periods of rotary pursuit separated by ten-minute rest periods. A measure of improvement throughout the test correlated negatively with both extraversion and neuroticism but neither correlation was significant. As the task is fairly difficult, these trends are in the direction which would be predicted but the main function of this study was to test the prediction that extraverts would show greater reminiscence than introverts owing to their postulated more rapid growth, higher maximum level and slower dissipation of reactive inhibition (I_R). Reminiscence scores were calculated by subtracting the mean time on target during the last three pre-rest ten-second periods from the time on target during the first post-rest ten seconds. There were two such scores for each subject corresponding to the two rest intervals: these were significantly inter-correlated ($r = 0.44$). The first reminiscence scores (R_1) correlated significantly and positively ($r = 0.29$) with subjects' extraversion scores (E) on the Maudsley Personality Inventory (M.P.I.) (Eysenck 1956a) while the correlation of E with the second reminiscence score (R_2) was insignificant. The neuroticism (N) scores of the M.P.I. also correlated significantly with R_1 ($r = 0.40$) and, at a level approaching significance, with R_2 ($r = 0.27$).

Eysenck argues that the lowered correlation between E and R_2 , like the relatively low reliability of the R scores, derives from the contamination of the second reminiscence scores, resulting from the development of conditioned inhibition (sI_R) during the latter part of the pre-rest performance and its extinction during early post-rest performance. Although no prediction was made concerning correlations between R and N, these were to be expected from the concept of N as a drive variable. Increased drive increases I_R tolerance and, therefore, allows greater reminiscence. The lower correlation with R_2 was explained in terms of sI_R development, as before.

From this argument, it follows that the degree of correlation between R scores and both E and N should increase in conditions unfavourable to the development of sI_R . Star (1957) aimed to achieve this by reducing the cycles of massed practice to ninety seconds, a time suggested by Eysenck (1956c) as approximating to that required for I_R to reach a critical level and initiate involuntary rest pauses. Four groups were selected in terms of E and N scores. One group (EN) included subjects scoring high for both E and N, one was low on both scales (en), one high on E and low on N (En) and one low on E and high on N (eN). These groups were given sixteen ninety-second cycles of massed practice separated by five-minute rest periods. It was predicted that group EN would show most reminiscence and en the

least with En and eN falling between. Similar predictions were made concerning relative depression of performance within cycles. These predictions would be valid only if appreciable sI_R development was prevented by the experimental conditions. Thus, on the basis of the theoretical argument outlined above and elaborated by Eysenck (1956c), two further predictions were made as a check on sI_R development. Firstly, it was predicted that no long-term warm up would be observed after rest-periods and, secondly, that all reminiscence scores would intercorrelate highly and a factor-analysis of the correlation matrix would suggest a single factor solution. Long term warm-up was, in fact, absent and, though the intercorrelations between R scores were low, they were non-random and generally positive and only a single common factor was extracted from the matrix. Thus Star considered that the development of any appreciable quantity of sI_R had been prevented. None, however, of the main predictions were confirmed at a significant level.

Star then replicated Eysenck's original experiment but added a fourth extended cycle of practice and employed his own apparatus. One hundred subjects were selected from a group of apprentices who were tested at their factory. There was again a significant correlation between E and R_1 and progressively smaller and insignificant correlations between E and R_2 and E and R_3 . The correlation between N and R_1 was also significant but negative: the correlations of N with R_2 and R_3 were insignificant.

Das (1957) included rotary pursuit among a battery of tests administered to a group of normal subjects. He used ninety-second cycles of massed practice, as in Star's first study, but ten-minute rest pauses as in Eysenck's study. He failed to demonstrate any significant correlation between either E or N and reminiscence. The observed correlation between N and R_1 was, however, again negative and its size was just short of that required for significance ($r = -0.24$). Star's analogous correlation was, in fact, identical in size but achieved significance owing to his larger experimental population. The same apparatus was used in Das's and Star's experiments and in a study by Bartholomew and Marley (1957) which replicated Star's original study both in its design and its results: no significant relationships were observed between reminiscence and M.P.I. scores.

Thus it appears that, for rotary pursuit, ninety-second cycles of massed practice and, possibly, five-minute rest periods are insufficiently prolonged to allow the demonstration of significant relationships between reminiscence and personality variables but with five-minute practice periods and ten-minute rest periods these relationships become evident. Extraversion, as

measured by the M.P.I., is positively correlated with reminiscence but the latter's correlation with neuroticism may be either positive or negative, according to experimental factors as yet undefined. These relationships can only be demonstrated for the first reminiscence score, with which later reminiscence scores are only moderately correlated.

whereas performance at the beginning of the second practice period will be a function of—

$$D \times (sH_R - sI_R)$$

Reminiscence, the difference between these two values, will not be a function of I_R alone but of—

$$I_R \times (sH_R - sI_R)$$

FIG. 13.8. THEORETICAL CURVES OF PERFORMANCE DURING MASSED PRACTICE OF ROTARY PURSUIT, ASSUMING HYPOTHESIS A

It seems to the writer that the predictions made by the authors of these studies are not based on a sufficiently elaborate theoretical analysis of the reminiscence phenomenon and, as the predictions depend as much on the learning theory as on the personality theory, it is considered justified to make such an analysis here. During an initial period of massed practice, sH_R , I_R and sI_R will grow at independent rates and interact to produce a complex curve of performance. During the subsequent rest period I_R will dissipate but sH_R and sI_R , being habit states, will remain relatively unchanged. Thus, at the beginning of the second period of massed practice, the initial sE_R will be at a higher level than at the end of the first period of practice, the difference being reflected in the phenomenon of reminiscence. This reminiscence, however, while being a consequence of the dissipation of I_R is not, quantitatively, a function of I_R alone. From the equation described earlier, performance at the end of the first practice period will be a function of—

$$(D - I_R) \times (sH_R - sI_R)$$

sI_R and sH_R are minimal during the first of a series of massed practice periods and individual differences for these variables probably slight. I_R , if the rest period is sufficiently long to allow complete or near-complete dissipation, would be expected to develop to equal and considerable extents in each period. Thus the first reminiscence score should relate most closely to extraversion scores if the latter reflect individual differences in susceptibility to reactive inhibition.

sH_R would be expected to increase, according to the usual positive growth function, throughout the series until it reaches its asymptote. The same would be true of sI_R were it not for the discrimination process, resulting from fluctuations in the stimulus conditions, postulated by Eysenck (1956c) in explanation of the long-term warm-up phenomenon. sI_R , according to Hull, is a negative habit, the acquisition of which is reinforced by drive reduction resulting from the dissipation of I_R during the period when the response is not made. Such drive reduction can only occur when I_R has accumulated to some extent, i.e. after a certain period of massed practice. During the early part of a later period of massed practice,

when I_R is minimal, drive reduction can only occur in relation to positive drives and these are reduced by successful performance. Therefore, the negative reaction potential associated with an sI_R will tend to extinguish during the early period but sI_R is again reinforced later, as massed practice continues. This is essentially a discrimination learning situation and,

throughout, are graphically represented in Figs. 13.8 and 13.9. Fig. 13.8 is based on the additional assumption that the length of each massed-practice period is sufficiently long for I_R to accumulate to a level equal to that of drive and thus initiate a series of involuntary rest pauses (Hypothesis A), whereas Fig. 13.9 involves the contrary assumption (Hypothesis B) (See Fig.

FIG. 13.9. THEORETICAL CURVES OF PERFORMANCE DURING MASSED PRACTICE OF ROTARY PURSUIT, ASSUMING HYPOTHESIS B

The broken lines represent performance at an increased ($\times 1.5$) drive level.

after a series of massed-practice periods with intervening rest periods, sI_R would be expected to be operative when the drive stimulus corresponding to I_R is appreciable and inoperative when this stimulus is absent. Thus, while sI_R , and the individual differences associated with it, will appreciably affect reminiscence scores for the middle cycles of a series, later scores will be relatively less affected. The same is true for individual differences associated with sH_R . Subjects may differ in respect of their initial levels, rates of growth and asymptotes of sH_R but, when the asymptotes are reached, only the last of these can affect relative scores. Consistent with this argument, Eysenck (1956c) reports relatively high positive correlations within and between early and late reminiscence scores, positive correlations between the middle members of the series, and a low negative correlation between the two groups of scores.

Applying the above formula, theoretical curves of reaction potential during successive cycles of massed practice and rest, assuming the above theoretical analysis to be correct, applying arbitrary values to all the variables and assuming drive to be constant

13.10). It may be seen that the sE_R curves of Fig. 13.9 are of a form comparable to those empirically determined for the durations of practice used in the studies reviewed (Figs. 13.11 and 13.12), whereas the terminal low flat portion, inevitably associated with

FIG. 13.10. GROWTH OF REACTIVE INHIBITION DURING FIVE MINUTES' MASSED PRACTICE OF ROTARY PURSUIT, ACCORDING TO HYPOTHESES A AND B

hypothesis *A*, is absent from the empirical curves though such a tendency was evident during the prolonged fourth practice period of Star's second experiment. Hypothesis *B* does not imply that no sI_R would be acquired. The probability of the correct response is by no means 100 per cent, particularly during the early stages of learning. Oscillation and

competing response tendencies ensure that involuntary rest pauses will occur and allow some dissipation of I_R with which to reinforce the growth of sI_R .

Eysenck (1956c, 1957) suggests that hypothesis *A* is the more likely but, if I_R does in fact reach the level of drive and extraverts and introverts do not differ in their drive level, both groups would be expected to

FIG. 13.11. EMPIRICAL CURVES OF PERFORMANCE DURING MASSED (LOWER CURVES) AND DISTRIBUTED (UPPER CURVES) PRACTICE OF ROTARY PURSUIT
(After Eysenck, 1956c)

FIG. 13.12. EMPIRICAL CURVES OF PERFORMANCE DURING MASSED PRACTICE OF ROTARY PURSUIT
(After Eysenck, 1956c)

end a period of massed practice with equal I_R . Then, if the rest period is sufficiently long for most of the I_R to dissipate, even for those (extraverted) subjects in whom such dissipation is slow, no group differences in reminiscence could be predicted, at least as resulting from differences in the rate and level of acquisition of I_R . If the rest period is shorter, introverts, whose I_R will have dissipated more rapidly, should show greater reminiscence than extraverts. On the basis of hypothesis *B*, however, the positive correlation between extraversion and reminiscence is directly explicable in terms of Eysenck's postulates.

There remains, however, the problem of the correlation between neuroticism and reminiscence. Neuroticism is conceived of as a drive variable but drive is not one of the postulated determinants of reminiscence (I_R , sH_R , and sI_R). The broken lines in Fig. 13.9 represent reaction potential for the second and third periods of massed practice with a drive value 1.5 times as great as that assumed in calculating the lower curves. Though the former curves are at an overall higher level the amount of reminiscence is identical with that for the lower level of drive. Empirically, however, reminiscence is scored from average performances during the latter part of one practice period and the early part of the next. The curves for high drive, compared with those for low drive, have a steeper initial and flatter terminal slope. Both these factors would tend to augment empirical measures of reminiscence and would be expected to give rise to a positive correlation between reminiscence and drive. Experimentally increased motivation has been shown to increase reminiscence in rotary pursuit tasks by Kimble (1950) and Wasserman (1951).

This is consistent with Eysenck's initial experiment. Star, however, reports a significant negative correlation between neuroticism and reminiscence scores for his replication experiment. From an examination of these authors' empirical curves, Star's subjects, as would be expected from the nature of their employment (engineering apprenticeship), reached a higher average level of performance, after equivalent practice, than did Eysenck's subjects (academic students). That this results from a generally higher level of sH_R is consistent, according to the above analysis, with the greater average reminiscence shown by Star's group. Within his group, Star reports a marked tendency for those subjects with high *N* scores to perform less well than those with low *N* scores, while Eysenck reports a lesser insignificant tendency in the same direction. In terms of our general expectations concerning learning efficiency (Fig. 13.5), this would suggest that Star's subjects were in a situation of higher stress and/or were more neurotic than Eysenck's subjects. From the earlier theoretical discussion of the effects of stress,

it would appear that sH_R is the component of the basic learning equation deleteriously affected by stress. Its value is functionally diminished, either by competition from incorrect or irrelevant habit tendencies, or by the enhanced effect of such competing tendencies owing to increased generalization resulting from a strong drive element in the stimulus complex. Within a group, even when the general sH_R level is high, those individuals with higher drive will tend to show functionally lower sH_R and, hence, lower reminiscence scores when the stress conditions are such that the general level of drive is above the optimum. Then, in such a group, a tendency for a negative correlation between reminiscence and drive would be set against the tendency for a positive correlation deriving from empirical methods of measurement.

For this theoretical explanation to account for all the findings described, it would be necessary to demonstrate that both Star's and Das's subjects were appreciably more neurotic than those of Eysenck, or that they were subjected to considerably greater stress. The mean *N* score of Star's apprentices was higher than that of Eysenck's students but this difference failed to achieve statistical significance and Eysenck employed the more difficult task in that his turntable made 72 r.p.m. whereas Star and Das used a speed of 60 r.p.m. The fact that Star's subjects were tested in the context of a training course and, though volunteers were requested, the response was 100 per cent, is, possibly, indicative of stress. He also comments on a continuous background hum of machinery during his testing. Both Eysenck's and Das's subjects were more truly volunteers but the latter were subjected to a battery of procedures which included a first experience as a hypnotic subject. Thus a case can be made in support of the present analysis but the argument must remain tenuous until experiments have been performed in which the stress variable is systematically controlled.

Treadwell (1956) tested Eysenck's postulates concerning the relationships between introversion-extraversion and motor learning by use of a track-tracing task and the "Thinking" (*T*) scale of the Minnesota T.S.E. Introversion-Extraversion Questionnaire (Evans and McConnell, 1941). Two groups of twenty subjects with extreme scores on this scale were employed in an experiment of $2 \times 2 \times 2$ factorial design in which practice periods of 108 and 459 sec and rest periods of 5 and 10 min were systematically varied. Significant results were obtained consistent with all the specific hypotheses tested. These were—

1. A group of extraverts will exhibit more reminiscence than will a group of introverts equivalent in initial learning ability and granted an equal rest period.

2. Because extraverts develop reactive inhibition more rapidly than introverts, this relative superiority in reminiscence scores will be proportionately greater after a short than after a long practice period.

3. Because reactive inhibition dissipates more slowly in extraverts, their relative superiority in reminiscence scores will be proportionately greater after a long than after a short rest period. The confirmation of the second of these predictions suggests that, for the longer of the two practice periods used in this experiment, which is appreciably longer than that used by Eysenck, reactive inhibition does reach the level of drive in the more extraverted subjects. The author quotes examples of rest pauses taken by some of her subjects, towards the end of this period, during which they ceased work completely.

Unfortunately, Treadwell's test of extraversion is different from that used in the Maudsley studies. The available evidence indicates that the two measures are unrelated in that Jensen (1957) found significant correlations between the E scale of the M.P.I. and the Minnesota S ($r = 0.81$) and E ($r = 0.21$) scales, but no correlation ($r = 0.05$) with the T scale. The subjects in Treadwell's study were also tested with the M.A.S. The "anxiety" scores, though correlating significantly with the Minnesota E Scale, ($r = +0.26$) showed no significant correlation with the T scale or with the subjects' reminiscence scores ($r = 0.03$). This would be consistent with the previous theoretical analysis if the stress level in this experiment was intermediate between those in the Maudsley experiments. The author, however, suggests that there was little variance in neuroticism among her subjects and the scores obtained on the M.A.S. support this view.

(Broadbent (1956) describes experiments on fatigue in human subjects demonstrating that repeated stimulation, without repetition of response, produces inhibitory effects on performance. Individual differences in such "fatigue" decrements, in subjects performing inspection or watch-keeping tasks, were found to be large and to correlate significantly with tests found to distinguish hysterics from dysthymics. These findings are consistent with Eysenck's theory and with his argument that reactive inhibition is a central rather than a peripheral phenomenon.)

Eriksen (1954), using three different size squares as stimuli, related stimuli generalization to scores on the "Hysteria" (Hy) and "Psychasthenia" (Pt) scales of the M.M.P.I. Shock was administered to the subjects in one of two ways but all subjects received equal numbers of shocks. In the "avoidance" condition the subjects were told that failure to respond rapidly would be punished by shock, while the "non-

avoidance" group were told that they would receive random shocks. The "avoidance" condition, as would be expected, resulted in greater generalization. The high Hy scorers exhibited more generalization than high Pt scorers in both conditions, a finding explained by the author in terms of breakdown of the defences against anxiety of the former group, as postulated by Deese, Lazarus and Keenan (1953). Taylor (1956) argues that these findings do not invalidate those of Rosenbaum, previously described, as the correlations between these scales and the M.A.S. is low. In terms of our dimensional framework, the Hy and Pt scales would both be expected to measure neuroticism, while Hy would also, to some extent, measure extraversion and Pt introversion. Neuroticism, as a drive variable, would be expected to increase generalization but there is no basis for deciding which group of subjects is the more neurotic. When the strength of the response tendency to the positive stimulus is controlled, as it was in Eriksen's study, there is, as described earlier, no clear theoretical basis for deciding whether introverts or extraverts will respond more to the negative stimuli.

Of related interest is the investigation by Warren and Grant (1955) into the relationship between conditioned eyeblink discrimination and the "psychopathic deviation" (Pd) scale of the M.M.P.I. In terms of Eysenck's theory, subjects scoring high on this scale would be expected to tend towards both high neuroticism and high extraversion. This is consistent with these authors' report of a correlation of $+0.51$ between this scale and the M.A.S. The positive and negative stimuli were similar to those used by Hilgard, Jones and Kaplan and described earlier. High and low Pd scorers showed no significant difference in their responses to the positive stimulus but the high scorers made significantly more responses to the negative stimulus and, therefore, achieved poorer discrimination. In terms of the neuroticism dimension the high Pd group would be expected to respond more to both stimuli and to discriminate less well but, for the positive stimulus, this would be offset by the poorer learning associated with extraversion. As stated above, the theoretical prediction concerning extraversion and the negative stimulus is uncertain but this study and that of Eriksen would suggest that extraverts discriminate less well than introverts. In Eriksen's study, however, shock was administered and the hypothesis of Deese *et al.* may apply.

All the studies reviewed so far have involved laboratory experimentation but similar relationships have also been shown to apply in real-life learning situations. Thus Lynn (1955) reports that scores on an anxiety questionnaire are positively and significantly correlated with reading achievement for children of ages from seven to eleven years. He acknowledges that anxieties

to a degree beyond that characteristic of his group are likely to be related to scholastic retardation, as reported by authors such as Schonell (1942), and reports some confirmatory evidence from within his own data. Phillips and his associates (Gerard and Phillips, 1953; Phillips and Cowitz, 1953; Feffer and Phillips, 1953) present evidence indicating that individuals who perform inadequately under experimental stress conditions, irrespective of intellectual ability, are low in "social attainment" as measured by such factors as educational attainment, occupational status and acceptance of social responsibilities.)

Sarason and Mandler's (1942) report concerning the relationship between scores on their questionnaire of "test anxiety" and performance in college examinations has already been mentioned. (Furieux (1956) found striking relationships between "neuroticism" and "introversion-extraversion" as measured by Guilford's D.C. and R. scales (cf. Eysenck, 1953), examination performance and measures derived from his cognitive tests)(cf. Chapters 5 and 6 by W. D. Furieux and R. W. Payne). When the four groups representing neurotic introverts (N.I.), stable introverts (S.I.), neurotic extraverts (N.E.) and stable extraverts (S.E.) were compared, it was found that the N.I. group was most successful in high level University examinations and the S.E. group least successful. Within the N.I. group, those who gave evidence of actual psychiatric disturbance did less well than those included only by reason of their test scores but remained superior to the other groups. This pattern was not evident for lower level examinations when, however, differences in cognitive ability were larger and accounted for more of the variation in examination marks. These findings are consistent with Figs. 13.5 and 13.6 and with those of Sarason and Mandler.

(Janis and Feshbach (1953) presented illustrated lectures on dental hygiene to groups of High School students. The lectures were varied so as to evoke three intensities of fear motivation by including varying degrees of reference to and illustration of the tissue damage and pain resulting from dental caries. The degree of fear appeal correlated with the degree of affective reaction reported by the subjects on a questionnaire. All three levels of fear motivation were equally effective for teaching the facts of dental hygiene but, in terms of modification of actual behaviour, only the lecture with minimal fear appeal had any effect.) In a later paper (Janis and Feshbach, 1954) these authors report the scores of these subjects on an anxiety questionnaire and their finding that anxious subjects, as compared with non-anxious, were consistently less influenced by strong fear appeal but were more influenced by the lecture with minimal fear appeal. These results are entirely consistent with our theoretical expectations but a rather different follow-

up study by Moltz and Thistlethwaite (1955) failed to reproduce the findings and showed that anxiety reduction, induced by reassurance, was not associated with increased learning or greater behavioural conformity with the "message" of the lecture.)

(The number of investigations into the learning characteristics of actual neurotic patients is unfortunately small and theoretical advances in this area will require far more studies of this type. Those concerned with classical conditioning were discussed in the previous chapter where Franks cites evidence to show that, whereas introversion-extraversion is related to conditionability, neuroticism is not so related. Strength of drive may well be irrelevant to the conditioning situations described but this should not be true of experiments concerned with the acquisition of conditioned drives, analogous to those described in the earlier discussion of traumatic avoidance learning in animals,) but no experiments of this type have been carried out with neurotic subjects. Indeed, as Jensen (1958) pointed out, though a few experiments with human subjects have used a conditioned stimulus in avoidance situations, and measurements consistent with the development of a C.A.D. have been recorded (e.g. Wickens and Platt, 1954; Lacey, Smith and Green, 1955; Brothers, 1956) in no instance has the reduction of such a C.A.D., by the avoidance of the conditioned stimulus, been used to reinforce new instrumental learning in a different experimental setting. An empirical demonstration of this nature would do much to strengthen the bridge between experimental work on animals and theories of human learning.

Rosenbaum (1956) included in his study of stimulus generalization, described earlier, groups of psychiatric patients as well as normal subjects. These were divided into anxious and non-anxious subgroups in accordance with psychiatric ratings of anxiety. The results were, in the main, parallel to those for anxious and non-anxious normal subjects but, as many of the patients were diagnosed as schizophrenic, the implications are difficult to evaluate. Buss (1955) carried out a somewhat similar study with psychiatric patients of unspecified diagnosis but divided into two groups in terms of M.A.S. scores. With blocks of differing heights as stimuli, the anxious group made relatively more positive verbal responses at each test point and showed a flatter generalization gradient but these differences failed to achieve significance.

(Matarazzo and Matarazzo (1956) and Korchin and Levine (1957) included psychiatric patients among their subjects for the experiments described earlier. The former authors found no difference in learning scores on their pursuit-meter task between psychiatric and other patients in their hospital sample.) Korchin and Levine found that anxious patients behaved like

anxious non-patient subjects but to an exaggerated degree, as would be expected. Diethelm and Jones (1947) studied the learning and retention of a stylus maze task by a group of depressive and psychoneurotic patients displaying anxiety among their most prominent symptoms, and showed that their efficiency increased when their anxiety subsided.

Pascal and Swensen (1952) report that psychoneurotic patients improved significantly less, during practice on a complex discrimination reaction-time task, than did normal control subjects. With the introduction, in an avoidance context, of a loud white noise, however, their performance improved to a level only slightly below that of the control subjects. If the noise is considered a stressor, this finding is inconsistent with expectations based on Fig. 13.5 and in a direction similar to the results of Silverman and Blitz (1956) and Deese, Lazarus and Keenan (1953) with anxious and non-anxious normal subjects. In this instance, however, an explanation in terms of an hysteria-psychasthenia dimension is inapplicable.

(Taffel (1955) successfully modified the verbal behaviour of psychiatric patients by reinforcing with the word *good* any response sentence beginning with a pronoun of self-reference (I or We). Neither the relation between his responses and the experimenter's comments, nor the purpose of the experiment, was discovered by any of the subjects. The experimental group contained both psychotic and neurotic patients and was not subdivided in terms of diagnosis. All subjects were tested, however, on the M.A.S. and their scores were positively and significantly related to the measures of learning. This relationship tends to indicate that, among the neurotic subjects, the dysthymics learned most effectively.)

(Malmo and Amsel (1948) compared the learning of severely anxious patients and control subjects, using serial lists of eight nonsense syllables. Overall, the patients were inferior but, when serial position curves of error were examined, though these displayed the usual "bowing" effect, they were significantly higher in the patient groups only at the early positions in the series. The same was true of serial position curves of "oscillations at the threshold of recall" as measured by the mean number of presentations between the first success and last failure at each position.) These findings are contrary to those which would be predicted from either the Iowa or the "frustration by difficulty" hypotheses described earlier: they are explained by the authors in terms of the hypothesis that patients show, in addition to intra-list interference effects, the effects of interference from anxiety mediated responses. They further suggest that this interference is maximal at the start of a trial but is voluntarily inhibited with an increase of drive resulting from failure with the early syllables. Willett

(1958), using normal subjects and concerned mainly with the effects of drugs on serial verbal learning, found that subjects with high N scores on the M.P.I. required more trials and made more oscillations than low N scorers but these differences led to increased "bowing" of the serial position error curves for the neurotic subjects, thus indicating maximal interference with learning at the central positions in the series. The possible interrelationships between intra-series interference effects and personality variables are numerous and complex, and merit considerable further investigation. In view of the paucity of relevant data a theoretical analysis will not be attempted here.

(Hall and Crookes (1952) compared the performance of normal and psychoneurotic subjects on two learning tasks. For a series of ten word-pairs, the normal group was significantly superior, both in terms of recall and for scores relating to the regularity of their individual learning curves. The second task involved the learning of a sequence of five position combinations for a bank of three switches operated by the subjects.) Again the normal group was significantly superior on a learning score and tended to have more regular individual learning curves. A third score, "trial and error," referring to the number of switch movements made by the subject when the correct combination was incorrectly recalled, and a fourth score, the average time per response, failed to reveal any significant differences between the two groups. The neurotic subjects included thirty-nine patients with anxiety symptoms, nineteen with reactive depression, seven hysterics and six obsessionals, thus forming a mainly dysthymic group. Differences between the subgroups are difficult to evaluate, owing to differences in number, age and sex. On the verbal task the hysterics tended to improve least and produced the least regular curves. On the performance task, the anxious patients were in all respects more similar to the normal group than were the depressives. The obsessionals employed most "trial and error" and hysterics the least. (Compared with the control group, the neurotics showed, in general, less impairment on the motor than on the verbal task. Both tasks required the learning of series of associates, five triple motor associates and ten paired verbal associates. Internal interference factors and relative stress are difficult to assess.)

Brengelmann (1954, 1958a, 1958b) carried out a series of investigations, employing his Figure Reconstruction Test (F.R.T.) (see Chapter 3 by J. C. Brengelmann), scores on which are relatively independent of age and intellectual level. In his major studies of learning (1957a) he used one of the most difficult versions of this test, which required the drawn reproduction of two patterns of shapes immediately

following their successive exposure for five seconds. Among other scores, the mean angular displacement of the response shapes from their stimulus positions were calculated over a series of such trials (rotation error). Marked practice effects were evident and were consistently and significantly greater for the control group than for neurotic subjects, though the two groups were not significantly different during the early trials. When the neurotic patients were subdivided into hysteric and dysthymic groups, there was no significant difference in learning ability between the subgroups but the hysterics, fairly consistently, tended to be slightly superior and in a later study (1957b), mainly concerned with "immediate memory" but including some data on learning, the hysterics were significantly superior to dysthymics when the exposure time was only two seconds, but no difference was evident with thirty seconds exposure. In these experiments, questionnaire measurement of neuroticism and introversion-extraversion within the control groups disclosed relationships with learning essentially similar to those described. For these relationships to be consistent with our theoretical expectations, the experimental conditions must be such as to merit placement to the extreme right of the abscissa of some variant of Fig. 13.6. The brief stimulus exposure would probably make the situation fairly stressful but scarcely to the required degree. In terms of difficulty, however, this version of the F.R.T. was specifically selected as extreme and, during the first trials, the subjects' error scores were scarcely superior to those for random responses. Furthermore, as described, the experimental variation of the exposure time and, therefore, of difficulty, produced changes in the relative efficiency of hysterics and dysthymics consistent with some version of Fig. 13.6.

Lykken (1957) included an ingenious shock-avoidance learning task in a battery of tests administered to patients diagnosed as psychopaths and to normal subjects. The former were subdivided into two groups: (1) "primary sociopaths" according to Cleckley's (1950) criterion of lack of the normal affective accompaniments of experience; (2) the remainder, described as "neurotic sociopaths." Both categories scored lower than the control group on a specially designed anxiety scale with no loading on a neuroticism factor and negligible correlations with the M.A.S. and the Welsh (1952) Anxiety Index. The latter scales, considered mainly measures of neuroticism, produced relatively high scores for the neurotic psychopaths and equal scores for the other two groups. In terms of Eysenck's dimensions, the primary sociopaths (group I) were presumably very extraverted and non-neurotic (very high inhibition, low drive), the neurotic sociopaths (group II) extraverted and neurotic (high inhibition, high drive) and the control

group (III) ambivert and non-neurotic (average inhibition, low drive). Consistently with Fig. 13.5 and moderate stress, group III showed most avoidance and group I least. The difference between groups I and III and that between II and III was statistically significant.)

Conclusions

This study completes our review of the experimental literature. (From the review it is abundantly clear that our preceding formulation of theoretical expectations was altogether too flexible for precise validation. Whereas the great majority of the studies reviewed produced results consistent with that formulation, this consistency was only achieved after a *post hoc* placement of the experimental situation along the stress-difficulty dimension. The relative difficulty of the experimental task is clearly of importance in determining the nature and direction of group differences in learning, and may well be the most important single factor. Furthermore, it is a factor which can be objectively and quantitatively controlled, as in the important experiment by Saltz and Hoehn (1957), but most investigators have failed to exercise this control.)

Stress is, by contrast, a nebulous concept, the quantification of which is scarcely possible, but the stress situations devised by many investigators clearly affected the performance and probably the learning efficiency of their subjects, and differentially affected groups selected in terms of personality variables relevant to abnormal psychology. Indeed, it seems likely that the relatively mild stresses of laboratory situations have clearer and more predictable effects on psychological performance than on the physiological variables usually measured in experimental situations (cf. Chapter 11 by I. Martin). Psychological stress, induced by such devices as failure stimulation, generally interacted with personality variables in a manner consistent with our theoretical expectations, but the complexity of the factors contributing to "psychological stress" was evident in many studies. The main departures from expectation, and those most difficult to reconcile with current theories, resulted from the application of direct painful stimulation, such as electric shock, or the threat of such application. In three of the studies reviewed, situations of this type tended, in some circumstances, to improve the performance of subjects of presumably neurotic tendency and to impair that of more stable subjects. As mentioned in an early section of this chapter, a strong C.A.D. may derive from repeated mild traumata. The conditioned stimulus may then produce a stronger "punishment" effect than the reintroduction of the original trauma. It is possible that some mechanism of an analogous nature is

responsible for the present aberrant findings, but it would be difficult to frame a testable hypothesis in these terms.

The imperfect consistency between the empirical results and our theoretical discussion undoubtedly derives, in part, from the fact that the latter was exclusively concerned with the personality dimensions of neuroticism and introversion-extraversion. This does not imply that the writer considers that other personality traits do not have important effects on learning. Indeed, the evidence reviewed indicates that the proportion of inter-individual variation accounted for by these factors may be relatively small. Deese and his co-workers (Lazarus, Deese and Osler, 1952; (Deese and Lazarus, 1953) emphasize the importance of differences in individuals' perception of "threat" in stress situations and differences in *style*, as illustrated by Davis's (1948) experiments. Davis, using a simulated aircraft cockpit and other laboratory situations involving skills related to air pilotage, found that fast pacing tended to disorganize the performance of subjects displaying neurotic tendencies. Within this group, hysterics persisted in a slow but stable rate of response, thus achieving a moderate score by responding only to a proportion of stimuli. Dysthymics, however, tended to become overactive, ineffectively attempting to respond to every stimulus change, and thus achieving a lower score. As pointed out by Lazarus and Deese, the dysthymic style might, with a different task or different method of scoring, produce the higher score. Venables (1955) demonstrated the importance of such an overactivity-inertia continuum in a motor task, and its interaction with personality factors and task difficulty.) Within a group of normal subjects, those scoring in the extraverted direction on a battery of tests showed a significant tendency to become more inert with increased difficulty of the task, while introverted subjects become more active. Similar tendencies were evident for hysteric and dysthymic groups of neurotic patients, except that the hysterics tended to show equal inertia at both difficulty levels. This particular trait may reflect the differences in the balance of neurological excitation and inhibition, postulated as underlying the introversion-extraversion dimension, and may account for some of the effects of stress on subjects with low M.A.S. scores demonstrated by Deese, Lazarus and Keenan (1953) and Silverman and Blitz (1956).

Brengelmann (1957b) reports significant relationships between scores on a test of "rigidity" and learning scores on the F.R.T. Wesley (1953) studied the relationships between scores on a rigidity questionnaire, M.A.S. scores and performance on a series of concept-formation tasks of the card-sorting type. The subjects were divided into a rigid group, with high

rigidity and low anxiety scores, an anxious group, with high anxiety and low rigidity scores, and a normal group with low scores on both scales. There was no significant relationship between the M.A.S. and rigidity scores but scores on each scale were related to learning efficiency. The anxious group required least trials to learn to the criterion on all four sorting tasks, required least trials to shift "set" and made least perseverative responses. Overall, these trends were not statistically significant but, when individual differences in initial learning were controlled, the rigid group required significantly more trials to shift set and made significantly more perseverative responses than the other groups. Grant and Patel (1957) used a similar task in an experiment involving shock and threat of shock. High scorers on the M.A.S. made relatively few perseverative and non-perseverative errors early in the series but, during the later stages when, presumably, the strength and number of competing responses were maximal, their relative performance deteriorated. Weiss (1957) made use of a specially designed test of perceptual rigidity, derived from the Lewinian concept of boundary impermeability, and found, as he predicted, that subjects who transposed in a size-discrimination learning task achieved low scores on this test, while those who failed to transpose achieved high rigidity scores.

Harley (1957) demonstrated a relationship between "achievement imagery" (A.I.) scores on the I.P.I. test (Hurley, 1955) and serial verbal learning, such that low A.I. scorers anticipated relatively few correct nonsense syllables with low motivation instructions, but low and high scorers were equally efficient with high motivation instructions. Performance also correlated negatively with hostility and insecurity scores derived from this test but, unlike the other findings, the correlation with insecurity was not confirmed in a second, more elaborate study. Johnston (1955) reports that high A.I. scorers were more efficient than low scorers in learning a stylus maze under neutral instructions but, with threat of shock, there was no significant difference between the groups. Similar significant difference between achievement imagery, learning efficiency and motivating instructions are reported by Williams (1955). (Also related to Hurley's findings are those of Smith (1953) who reports an interactive relationship between expressed hostility, the paired-associate learning of words with hostile or non-hostile connotations and neutral or failure-stress conditions. Non-hostile subjects were impaired in their learning of hostile words after failure stress, whereas hostile subjects were similarly impaired in learning non-hostile words.) (Individual differences in modes of defence against anxiety have already been mentioned and may have

been important in the determination of the pattern of results in such studies as those by Deese, Lazarus and Keenan (1953), Eriksen (1954) and Hamilton (1957a). Other dimensions along which important individual and group differences may occur have been suggested by Lazarus, Deese and Osler (1952), Farber (1955) and others, but little evidence is available concerning the relationships between traits other than those considered and learning efficiency. Further

experimentation is likely to produce such evidence and to throw light on the interrelationships between the traits already described. One advantage of the dimensional framework adopted here is that both neuroticism and introversion-extraversion represent differences at the type level and are derived from the intercorrelations between scores appertaining to many lower-order traits considered relevant to abnormal psychology (cf. Chapter 1 by H. J. Eysenck).

LEARNING AND PSYCHOSIS

The transition from the predispositional state of psychoticism into the state of manifest clinical psychosis seems much less dependent upon precipitating factors such as life-stresses than is that from neuroticism into clinical neurosis. (It cannot then be argued that psychosis is a learned disorder, as was argued earlier for neurosis, nor are there strong theoretical reasons to postulate that individual differences in respect of learning variables play an important dynamic role in psychotic processes.) Thus, in this section, the procedure adopted will be the reverse of that employed in the discussion of neurosis. The empirical results of investigations into the learning efficiency of psychotic patients will be examined for their theoretical implications and such generalizations as are possible made subsequently.

As impairment of learning is not generally regarded by clinicians as an important characteristic of functional psychosis, experimental studies of this function in psychotic patients are relatively few, at least in recent years. The more numerous studies during the early decades of this century were marred by several deficiencies such as inadequate control data, lack of statistical evaluation of the results and the inclusion within the same, usually small, experimental groups of patients from various diagnostic categories. Owing, presumably to a unitary concept of "insanity," the results were not usually examined for differential effects of different diseases and, as the groups frequently included a majority of brain-damaged subjects, the reported findings refer mainly to these. Because of these limitations, these early studies, which have been reviewed by such authors as Brody (1942), Hunt and Cofer (1944) and Campbell (1957), will not be described here but the most consistent or suggestive findings are noted below.

(It is clear that both manic-depressive and schizophrenic patients are capable of learning, in that their performances improve with practice, but it seems likely that, despite this improvement, their learning ability is somewhat impaired compared with that of normal subjects. The latter finding is by no means universal and allowance was rarely made for the

patient's initial performance, which was generally below that of control subjects. Simmins (1933) found a group of functional psychotics no worse than her control group on a series of short-term "memory" tests, when general ability (g) was controlled statistically. Hull's (1917) study of paired-associate learning suggests that any impairment observed tends to affect the impression rather than the retention stage of learning.) Also of interest are the consistent early findings concerning continuous work (massed practice) at simple tasks, reported by such authors as Kraepelin, Hoch, Wells and Currie (cf. Hunt and Cofer, 1944). Schizophrenics, after an initial period of sustained performance, appear to reduce output at an abnormally high rate whereas manic-depressive patients, whether in manic or melancholic states, exhibit a reversal of the usual "fatigue effect" by improving in performance prior to a delayed decline.

(Clinical testing procedures provide evidence that some degree of impairment of learning is characteristic of psychotic patients. Babcock and Levy (1940), for example, report lower scores for various groups of schizophrenic patients, when compared with normal subjects of similar vocabulary level and age, on a battery of tests of "mental efficiency," including tests of "initial learning" and "recall.") The rationale for this type of test has been criticized by Shapiro and Nelson (1955) but these authors, with a more adequate test procedure, demonstrated impaired ability for learning the meanings of words in co-operative chronic schizophrenic and manic-depressive patients. A group of acute schizophrenics showed no learning impairment.

4. Hall and Crookes (1951) report on the performance of thirty-five schizophrenic patients, mainly in an early acute stage of their illness, while learning the verbal and motor tasks used in these authors' investigation of the effect of neurosis on learning, and described earlier in this chapter. Compared with normal subjects of comparable age and vocabulary level, these patients, despite considerable group overlap, were, on the average, significantly inferior in terms of learning scores and produced markedly irregular learning

curves for both tasks. During their learning of the switch combinations, the schizophrenics tended to adopt a haphazard unsystematic trial-and-error approach and, during their learning of the word-pairs, words, commonly associated with the stimulus words, intruded among their responses. In general, the schizophrenic performance was suggestive of increased competition from previously learned responses and, possibly, of increased oscillation of response tendencies, though certain individuals showed perseverative trends. Bonnet (1953) similarly demonstrates a wide range of abnormalities in learning curves produced by psychotic patients working at a cancellation task.

(Bregelmann (1958a), in the course of his experiments with the F.R.T., described earlier, tested forty-three psychotic patients in addition to the groups of neurotic and normal subjects. Seven of these were endogenous depressives and the remainder schizophrenics. For all the learning scores, the psychotics were significantly inferior to the control group and, frequently, they were significantly below the neurotics. Consistent with the level of difficulty of the task, there were no significant differences in error scores during the early trials.)

(Many of the early authors consider the difficulties in learning shown by psychotic patients to be secondary to more fundamental abnormalities of attention, co-operation or motivation.) A similar view is advanced by Hunt and Cofer, who point out that the performance of schizophrenics is very variable but that increases of output can be obtained if the investigator makes efforts to gain the patients' confidence and co-operation. On the basis of this evidence and a variation in autonomic activity, concomitant with the variations in output, these authors consider that the deficit in schizophrenia is one of motivation rather than one of capacity.

Rather similar conclusions were reached by Huston and Shakow from the evidence of a long series of investigations into learning and other functions in schizophrenia. They noted that schizophrenics improved in terms of increased accuracy and decreased variance on pursuit-meter and prod-meter tasks (Huston, 1932; Shakow, 1932). A similar improvement occurred in speed of tapping over successive trials and widely separated sessions, while normal subjects failed to improve on the tapping task (Huston and Shakow, 1936). The major portion of the initial variance in speed was attributed to differences in the schizophrenics' co-operation as it was measured by behaviour ratings during the test sessions and which, therefore, are likely to be determined in part by the nature of the performance with which they are later correlated. In papers describing experiments on reaction-time (Huston, Shakow and Riggs, 1937,

Rodnick and Shakow, 1940) this concept of "lack of co-operation" was defined in terms of an inability to maintain an appropriate level of mental preparedness or set. Studies of manual steadiness (Huston and Shakow, 1946) produced results similar to those of other tasks. Compared with normal control subjects, schizophrenic patients were initially less steady and more variable but improved with practice, as did the control group. Ratings of co-operation showed an appreciable correlation ($r = +0.62$) with the steadiness scores and the initially least steady patients improved most with practice. In later studies (Huston and Shakow, 1948, 1949), schizophrenics, manic-depressives and normal control subjects practiced rotary pursuit for sessions of ten trials each at intervals of three months. Both the manic-depressive and normal groups improved significantly more than the schizophrenics, who had the poorest score initially. Again test scores were related to ratings of observed co-operation but those schizophrenics who merited the top rating for co-operation still failed to achieve scores equivalent to those of the normal subjects. When the apparatus was modified so that movement occurred only when the stylus was in contact with the target (prod-meter), the schizophrenics again showed impaired performance but improved considerably with practice. A group of schizophrenics, given prolonged practice at this task and aided by various motivational devices, finally achieved a level of performance only slightly below that typical of normal subjects.

(Throughout this series of experiments, a consistent trend was noted for paranoid schizophrenics to behave most like normal subjects, both in terms of co-operation and test performance, while catatonics showed the greatest deficit and hebephrenics occupied an intermediate position. In general, Shakow (1946) considers that, while lack of co-operation is of major importance, psychosis has a specific effect on performance, particularly when the task is complex. Learning curves for schizophrenics are considered essentially similar in shape to those typical of normal groups and the characteristic lack of co-operation to derive from personal systems of incentives.)

O'Connor, Heron and Carstairs (1956) investigated the motivation of schizophrenics more directly by setting a group of paranoid schizophrenics a button-sorting task for half an hour a day over twenty-eight days under various incentive conditions including encouragement, self-competition and payment by results. None of these conditions altered the rate of improvement but later studies (O'Connor, 1957a, 1957c; O'Connor and Topping, 1957) showed that money payments impaired the performance and learning of paranoid schizophrenics, both for laboratory tasks such as the learning of shapes by serial

anticipation and the incidental recall of the colours of these shapes, and for normal subcontract industrial work. With normal subjects and other categories of chronic schizophrenics this type of incentive led to an improvement of performance.

Cohen (1956) compared the performance of schizophrenic and control groups on tasks involving the learning of a series of motor responses to successive visual stimuli. Under neutral conditions and in conditions of increased motivation, induced by a shock-avoidance technique, the schizophrenics showed impaired learning ability. The results indicated a differential facilitative effect on the schizophrenics of the motivational situation, but only for the second of the two tasks employed.

Peters (1953) compared the performance of chronic and acute schizophrenics on a series of multiple-choice learning problems of graded difficulty. The chronic patients took many more trials to learn to the criterion and, unlike the acute patients, tended to adopt stereotyped responses, repeated trial after trial, despite verbal guidance by the experimenter. Peters relates these stereotyped responses, in terms of their non-adaptiveness and difficulty of extinction, to those made by the rats in Maier's (1956) frustration studies and postulates that, although his subjects were ostensibly motivated by hunger from deprivation and insulin shock, they were unable to maintain a goal orientation, owing to frustration. An alternative hypothesis, suggested by Peters, relates to Pavlov's concept of "pathological inertia" in schizophrenia. In support of these hypotheses, Peters and his collaborators (Peters and Jenkins, 1954; Peters and Murphree, 1954) present evidence that guided problem-solving of the type described beneficially affected the performance of schizophrenics on other tasks and their clinical status.)

The early findings concerning continuous work, described above, tend to suggest that schizophrenics are characterized either by low drive or by rapid development of reactive inhibition, while manic-depressives show the reverse pattern. As both groups tend to be worse than normal subjects in initial performance, a drive difference is the less likely. A differential susceptibility to reactive inhibition was earlier postulated as underlying the introversion-extraversion dimension but it has not been possible to separate the two psychotic groups in these terms (cf. Chapter 1 by H. J. Eysenck).

Venables and Tizard (1956b) followed up these early studies by comparing the performance of thirty non-paranoid schizophrenics and ten endogenous depressives on a continuous choice reaction-time task. The curves resulting from twenty minutes, massed practice, interrupted at the half-way stage by a one-minute rest period, are shown in Fig. 13.13. The

authors report a significant difference in level, but not in slope, between short- and long-stay schizophrenics the former being superior. The diagnostic groups differed significantly in slope, the depressives improving their performance steadily both before and after the rest period whereas the schizophrenics improved less before rest and their performance declined in the second period of practice. The schizophrenics also

FIG. 13.13. PERFORMANCE OF SCHIZOPHRENIC (—•—) AND DEPRESSIVE (---○---) PATIENTS DURING MASSED PRACTICE OF A CONTINUOUS MULTIPLE-CHOICE REACTION-TIME TASK (After Venables and Tizard, 1956b)

showed significantly more reminiscence than the depressive group.

Thus the findings are essentially confirmatory of the earlier studies and are interpreted by the authors in terms of differential susceptibility to reactive inhibition. This explanation was tested (Tizard and Venables, 1957) by applying an external distracting stimulus during a similar experiment, with the expectation that this would disinhibit the schizophrenics and improve their performance. A loud white noise was sounded from responses 21 to 30 during a series of fifty consecutive switching responses to a stimulus light. Without distraction, schizophrenics were characterized by a steady decline in reaction-time whereas control subjects improved. Distraction significantly improved the performance of non-paranoid schizophrenics but had no effect on paranoid patients. There was a positive correlation between ratings on a "social withdrawal" scale and the facilitating effect of distraction. Thus the hypothesis was supported but only for certain types of schizophrenia.

The authors also consider the alternative hypotheses that, in chronic withdrawn schizophrenics, the "central excitatory state" is lowered and increased sensory input has a non-specific facilitatory effect. Thus a generalized inhibitory state is postulated instead of the more specific reactive inhibition accumulated during the successive evocations of a response. This hypothesis was supported by the results of a further experiment designed so as to minimize the effects of reactive inhibition. Reaction-times to an auditory stimulus were measured under two levels of background illumination for thirty "sociable" and thirty "withdrawn" schizophrenic patients. The latter showed a significant tendency to react more quickly under bright than under dim illumination, whereas the former displayed an insignificant tendency in the reverse direction. The same authors (Venables and Tizard, 1956*a*, 1956*c*) elsewhere report results indicative of "paradoxical" effects on the relationship between reaction-time and stimulus intensity for chronic non-paranoid schizophrenics. It is argued that these findings are consistent with Pavlov's view of schizophrenic behaviour as resulting from a "weak inhibitory nervous system."

O'Connor (1957*b*) established groups of ten catatonic and ten paranoid schizophrenics and a control group, equivalent in age and intellectual status. These subjects worked for five minutes a day over two periods of five days, separated by a ten-day interval, at the task of underlining even numbers and cancelling odd numbers in lists of random numbers. As the task was practically error-free, this was essentially a speed test. There was no significant differences between the groups in respect of work decrement within trials, which occurred in all groups. Day-to-day improvement was greatest for the control group and least for the paranoid group. Reminiscence effects from the first to second set of trials were observable only for the control group. In this study the slope of the learning curves was linear in all groups but further work (O'Connor, 1957*c*) has consistently shown differences between the learning curves of paranoid and non-paranoid schizophrenics, the latter tending to display a negatively accelerated, curvilinear form and the former remaining linear over training periods of up to forty days.

The findings of Mailloux and Newburger (1941), who tested a large group of psychotic patients on a simple continuous choice reaction-time task similar to one used by Bills in a study from which Mailloux and Newburger derive their normative data are possibly related to some form of inhibition. Compared to the normal subjects of Bills's study, the patients displayed greater variability, a lower rate of response and more frequent and longer "blocks" in performance. No tests of significance were applied.

The investigation by Pascal and Swensen (1952), previously mentioned in the section on neurosis, is somewhat similar to that of Tizard and Venables though based on a different rationale. They report on practice effects for psychiatric patients and control subjects working at a complex discrimination reaction-time task over six trials of twelve responses each, separated by thirty-second rest intervals but with a longer interval between the fourth and fifth periods, during which a loud white noise was presented. This was subsequently sounded during the constant one-second fore-periods and terminated by a correct response. The schizophrenic subjects were insignificantly slower than matched control subjects at the commencement of training but improved significantly less until the introduction of the noise, which produced a marked increase in their speed of reaction and rendered their later performance little different from that of the control subjects. The schizophrenics were more variable than either the psychoneurotic or normal subjects. These authors interpret these effects by considering the noise a stressor and motivating device. Equally, it might be considered a disinhibitor, operating in the manner postulated by Tizard and Venables.

Bleke (1954) reports that, while no differences in learning or retention were observable between schizophrenic and control groups for a task requiring motor responses to a series of words analogous to the choice-points of a maze, those schizophrenics with an inadequate pre-morbid life adjustment showed greater reminiscence effects after a rest period than similar subjects with adequate pre-morbid adjustment or control subjects, but only in conditions of failure stress. Bleke considers that this cannot be due to increased reactive inhibition because no differences were observable in the pre-rest trials. Instead he postulates that the punishment condition produces interfering tendencies which inhibit effective performance and that these tendencies dissipate rapidly during the rest period. Bleke's own argument against reactive inhibition would be equally applicable to this explanation but the fact that the effect was only observed in punishment conditions contraindicates the reactive inhibition hypothesis. The fact that the effect only occurred with pre-morbidly inadequate patients suggests that the findings may not be related to psychosis as such but, possibly, to differences in neuroticism within the psychotic group. Similarly, as previously described, the usual relationships between M.A.S. scores and learning efficiency have been shown to apply within groups of psychotic patients. Robertson (1957), however, found no significant relationship between rated or admitted anxiety in the test situation and verbal learning scores for a hundred and twenty relieved and chronic psychotic patients.

(Campbell (1957) made a thorough attempt to evaluate the learning behaviour of psychotic patients in terms of the various parameters of learning established in experimental work with normal subjects. His approach derives mainly from three sources—

1. Zeaman and Kaufman (1955), who considered the effects of individual differences in the various major constructs of Hullian theory on the shapes of learning curves.

2. Fleishman and Hempel (1954, 1955), who factor-analysed the matrices of correlations between scores on complex learning tasks and various reference tests at various stages of learning. For each of two tasks, there was a specific factor which increased markedly in importance during practice. Group factors accounted for an appreciable proportion of the variance at the beginning of practice but were negligible at the end. Thus, the learning curve tends to reflect a change in the combination of abilities used by the subject at different stages of learning and the growth in importance of the specific factor is analogous to the growth of habit strength.

3. Reynolds (1952), who reports findings similar to those of Fleishman and Hempel and also examined the intercorrelations between trials of the learning task. He found that, as practice proceeds, the correlations between the first and last trials decrease, whereas those between successive trials increase. These tendencies were reversed by a rest pause but were re-established with continued practice. These findings were interpreted as reflecting the reinforcement of correct habits and the extinction of incorrect habits during practice. During rest, the reactive inhibition associated with the incorrect responses would dissipate and these responses would again interfere until the extinction was re-established.)

(On the basis of a general review of the literature and an analysis of the findings concerning effects of practice from a series of investigations into speed of performance in psychotic patients, carried out by himself and other co-workers of Shapiro (Nelson, 1953; Shapiro and Nelson, 1955; Kessell, 1955; Broadhurst, 1957), Campbell makes the generalization that, for sensorimotor tasks, improvement in speed is greater for psychotic than for normal subjects, but suggests that this results from their initial slowness. Within both psychotic and normal groups, improvement in speed is correlated negatively with initial speed and follows an independent course from improvement in qualitative performance.) Batteries of such tests produce generally higher intercorrelations within psychotic than within normal groups. (This evidence, he considers, is consistent with three hypo-

theses, not mutually incompatible, concerning the nature of learning in psychotic patients—

1. When presented with a novel learning task, psychotics start from a lower initial habit strength than normal subjects, i.e. they start lower on a negatively accelerated growth curve and, therefore, derive greater benefit from the early stages of practice. The most likely cause of their initial low level is a low degree of positive transfer from similar tasks, implying a true impairment of learning in the sense that each reinforcement produces a relatively small increment of habit strength. This might still allow a rise to the same asymptote as normal subjects.

2. Psychotics embark on a novel task with a higher level of generalized conditioned inhibition. With practice, normal subjects might develop this to an equal degree.

3. As psychotic patients display a high degree of affective disturbance, they might be considered to possess high drive which would interact with learning in the manner discussed earlier.

Campbell attempted to verify these hypotheses in an experiment with twenty schizophrenic, twenty depressive and twenty normal subjects. These were given massed practice over twenty trials, with a five-minute rest pause between trials 12 and 13, at tracing open paper-and-pencil mazes at three levels of difficulty and a modified version of the Ammons (1955) Pathways Test. All subjects were also tested on a group of reference tests concerned with general intellectual ability, speed of problem-solving, spatial ability and motor speed. Unlike Ammon's finding, the pathways test produced no learning curves nor did the rest pause produce reminiscence. All three mazes produced marked practice effects, the mean learning curves for the simplest maze being reproduced in Fig. 13.14. (For all mazes the abnormal subjects were slower throughout, but much more so at the commencement of practice. The depressives were, on the average, significantly slower than the schizophrenics.) The rest pause slowed down performance in all three groups but with no significant differences between the groups, though the trend was more marked in the abnormal groups.

Each individual's learning curve for each of the three mazes was then assessed in terms of starting level, asymptote, and rate of approach to the asymptote (growth constant). (The mean growth constant for the control subjects was significantly greater than that for the psychotics and the schizophrenics tended to produce higher constants than the depressives. The asymptotes differed significantly between all three groups, with normals highest and depressives lowest, even when the other two measures were controlled

statistically.) Campbell concludes that this analysis supports the view that the groups display different learning curves rather than different positions on the same curve. (The similarity of the patterns at all three levels of difficulty contraindicates the drive hypothesis and the inhibition hypothesis was not supported.) The correlations between trials were uniformly high for all

FIG. 13.14. PRACTICE GAINS IN SPEED OF MAZE TRACING
(After Campbell, 1957)

mazes and all groups. None of the expected trends of change were observed, even in the normal group. Similarly, the correlations between scores on the learning and reference tests remained high at every trial.

(Campbell's study has been described in some detail not because special importance is attached to the results obtained, which were in many ways disappointing, but because of its methodological sophistication.) The actual tasks used seem to have been inappropriate in that the phenomena observed by Fleishman and Hempel, Reynolds and Ammons were not reproduced, even by the normal group. This study would be well worth repetition, using tasks identical with those in the source studies. Careful description of psychotic learning in these terms would enable theory making to be placed on a sounder basis.

In this connexion, two parameters of learning, oscillation and stimulus generalization, rejected by Campbell as being unlikely to be of importance in psychotic performance, might well repay investigation by relating abnormalities of learning in psychotic patients with psychotic characteristics in other fields. One of the outstanding characteristics of psychotic performance is its variability, suggestive of an increased range of oscillatory potential (σ_{OR}) and it is of interest (that Hull (1917) found evidence of increased oscillation in abnormal subjects. In a simple learning situation involving a single stimulus-response connexion, as in conditioning, this would merely lead to lowered probabilities of response evocation during the early stages of learning and greater variability of response latency and amplitude throughout learning. In a complex situation, involving competing responses, enlarged ranges of fluctuation of response potentials would have an effect very similar to the diminished growth increment postulated by Campbell.) Thus, from Fig. 13.15, it can be seen that, with a doubled range of oscillation, the difference in strength between two particular response tendencies needs to be twice as great to retain the same probabilistic advantage for the stronger tendency. It is also evident that increased oscillation will allow subthreshold tendencies to enter the competition situation. These effects are very similar to those postulated by Spence and his colleagues as resulting from increased drive in complex

FIG. 13.15. COMPETING RESPONSES AT TWO RANGES OF OSCILLATION

tasks. The present hypothesis, however, generates different predictions concerning the relationships between simple and complex learning.

(“Overinclusion” (cf. Chapter 6 by R. Payne) implies an inability to exclude irrelevant material, suggestive of a flattened gradient of generalization in psychotic patients. The effect of such an abnormality is

illustrated in Fig. 13.16. If the distance S_2 to S_4 represents the range of stimulus generalization in normal subjects and S_1 to S_5 the equivalent range for psychotics it is clear that the presentation of S_3 will evoke many more response tendencies in psychotics than in normal subjects. Like the oscillation hypothesis, this would have the effect of increasing competition within a complex learning situation.)

(This hypothesis was tested specifically by Mednick (1955), who found a definite trend in this direction but this was significant for only one of the several measures used.) He also found, however, that, within

of increased stimulus generalization in psychosis but to a degree scarcely sufficient to account for the relatively gross abnormalities of learning demonstrated in some situations.)

Another promising approach to the objective description of learning in psychosis is that adopted by Lindsley, Skinner, and their associates (Lindsley, 1955; Raines, 1956), who apply Skinnerian methods of operant learning by adapting hospital rooms as man-size Skinner boxes. They have established high rates of lever-pressing responses with various schedules of reinforcement and a variety of incentives including

FIG. 13.16. RESPONSE COMPETITION AT TWO RANGES OF STIMULUS GENERALIZATION

S — R = Learned response tendency.
S - - - R = Generalized response tendency.

his schizophrenic group, measures of generalization were negatively and significantly related to the number of electroshock treatments received by the subject. As many had received such treatment this would tend to offset the overall trend. Garnezy (1951) also presents evidence of flatter generalization gradients in schizophrenic than in normal groups, both for geometric forms and for tones varying in pitch. The difference in gradients was minimal under reward conditions, but when failure stimulation was introduced, while the control subjects improved their discrimination, the schizophrenics made fewer responses to positive and negative stimuli and displayed a considerably flattened generalization gradient. Garnezy interpreted this finding as evidence of highly generalized withdrawal tendencies in schizophrenics. Chambers (1956) compared the performance of schizophrenic and non-psychotic patients on a "trial-and-error" sorting task and a task in which colour names were given to circles of different sizes. Only speed of performance differentiated the two groups on the former task but the schizophrenics made significantly more errors on the latter, and on several non-learning tasks also requiring discrimination.) Thus, (the available evidence supports the hypothesis

candy, cigarettes, coins, morsels of food, projected pictorial material and music. The reports to date are mainly concerned with the elaboration of the method but some tentative findings are reported. Among the more striking of these is the fact that, unlike normal controls, chronic schizophrenic patients tend to show occasional prolonged inter-response times and the frequency of these intervals appears to be correlated with the severity of psychosis. Very disturbed patients tend to continue at a low response rate despite reinforcement. Though performance in this situation is unrelated to verbal behaviour or to scores on psychometric tests, significant correlations with informal ratings of non-verbal ward behaviour and formal behaviour ratings have been demonstrated. In general, however, there is great variability in the response patterns produced by different patients, though small groups of patients may exhibit similar patterns. Some may display abnormalities of acquisition, some of extinction, while some may respond only to certain incentives or combinations of incentives. These groupings do not relate to psychiatric diagnostic categories. King *et al.* (1957), adopting this method, found that the operant response rates (pulling a plunger for candy and cigarettes) of thirty acute

schizophrenics showed a significant curvilinear relationship with severity of illness. There was some evidence, though insignificant, that improved clinical status changed the response rate in a manner predictable from the initial severity of illness by use of this regression line.

{The study by Salzinger and Pisoni (1957) who increased the proportion of statements expressing "affect" in the interview responses of schizophrenic patients by an operant conditioning technique, using verbal reinforcement of the now familiar *mmm-hm* type is of related interest. Individual differences in the learning curves were considerable and the steepest slope was produced by one subject later rediagnosed as manic-depressive. No normative data is yet available.}

O'Connor and Rawnsley (1958) used a simplified technique of this nature by which motor responses to a signal light were verbally reinforced with "good." The performance of groups of chronic paranoid schizophrenics, chronic non-paranoid schizophrenics and normal subjects differed significantly in this situation, whereas previously such differences were only observable during the extinction period of eyeblink conditioning. The paranoid subjects took significantly longest to condition with the verbal procedure and displayed modified responses after an interpolated simple mental task and when the word "light" was used instead of an actual light. The authors suggest that these findings may imply abnormalities of the "secondary signalling system" in paranoid schizophrenics. None of the learning scores showed any significant correlation with scores on an introversion questionnaire.

{The review of studies concerned with learning in functional psychosis, now completed, while disclosing many promising leads and much ingenious experimentation, reveals too many inconsistent and isolated trends and relationships to merit an attempt at a unifying theoretical analysis. At the same time, there is sufficient consistency within groups of findings to enable certain tentative generalizations to be made}

{ 1. Psychotic patients of all types are capable of learning.

2. Despite this capacity, when compared with normal or psychoneurotic subjects, psychotics display impaired learning efficiency but individual differences are considerable and overlap between groups is large.

3. This deficit may not, or not entirely, derive from a true impairment of learning capacity but may be a secondary effect of abnormal motivational or other processes.

4. In terms of learning processes, manic-depressives form a group distinct from schizophrenics.

5. Similarly, schizophrenics do not form a unitary group and paranoid schizophrenics, in particular, display specific tendencies.

6. Some types of schizophrenia may result in exaggerated inhibitory tendencies of a character yet undetermined.

7. Increased stimulus generalization may be characteristic of some types of schizophrenia.

8. Chronicity and severity of psychosis are related to the degree of learning impairment. }

Organic psychoses have not been discussed here as the psychological effects of brain damage are treated specifically in other chapters. { Senile psychosis is, however, one condition which may result from structural damage to cerebral tissue but may, equally well, be the consequence of a more subtle functional deterioration. "Memory disorder" is frequently considered of especial importance in this condition. Inglis (1958) has recently reviewed the relevant literature and concludes that there is ample evidence that patients diagnosed as suffering from senile dementia exhibit learning disabilities both in respect of acquisition and reproduction, whether by recognition or recall. This writer presents empirical and theoretical evidence to support his view that the learning dysfunction, which has far-reaching effects on cognitive functions in general, is related to metabolic changes of blood content in old age. }

CONCLUDING DISCUSSION

Although this chapter was intended to describe the effects of abnormal personality variables on learning processes, much of the discussion has necessarily been concerned with the nature of certain learning phenomena as such. Despite the ingenious hypotheses of learning theorists and the impressive output of experimental work on learning in recent years, theoretical explanations of the effects of such variables as task-complexity or the massing of practice remain uncertain. Clarification of many of the issues dis-

cussed here must await advances in learning theory as well as in personality theory. Recent elaborations of stochastic models and statistical learning theories promise such an advance but, at their present stage of development, they appear more useful for the description of behaviour in certain specific well defined situations than for the prediction of relationships over a wide range of behaviour. It would scarcely have been possible to assess the data reviewed in this chapter in the terms of any existing mathematical

model, nor indeed, in those of information theory, another approach of considerable potentiality.

Despite the difficulties of precise evaluation, the majority of investigations reviewed produced evidence of lawful interrelationships between personality variables, learning variables and experimental conditions and, in many instances, a marked tendency was displayed for these relationships to be of a curvilinear rather than a linear nature. In view of the latter finding, future investigators would be well advised to employ experimental groups representative of a wide range of any particular personality variable rather than groups selected in terms of extreme scores. Statistical techniques of evaluation and description must also be adapted to deal with non-linear trends. Factor analytic techniques, for example, can only represent correlations of equal size throughout the ranges of dimensions such as neuroticism and introversion-extraversion. It seems possible, however, that, while these two dimensions may be orthogonal in their middle ranges, extreme introverts, by reason of unrealistic ambitions and standards, may create for themselves life-stresses which increase the risk of neurotic breakdown whereas extreme extraverts, with lower standards and a tendency to ignore or avoid difficulties, may reduce the stress to which they are subjected. Some explanation of this nature may account for the frequent finding of a small but significant positive correlation between neuroticism and introversion, when these are measured by questionnaire methods (Jensen, 1957).

(The very complexity of the experimental findings accentuate the continuing need for careful and precise laboratory investigations. Clinical psychology cannot develop without experimental researches employing the methods of general psychology and these will inevitably lead to the mutual enrichment of both fields.)

CHAPTER 14

Psychological Effects of Brain Damage¹

V. MEYER

INTRODUCTION

ANYONE acquainted with the literature on the psychological effects of brain damage will agree that this field contains numerous controversial issues and that the findings do not permit a clear orientation. A vast number of isolated, disconnected studies have been reported, the results of which are equivocal, inconsistent, and very often contradictory; up to the present time no acceptable theory of brain organization and functioning has emerged from them and the diagnostic tests in this field show too high a degree of misclassification to be very useful for clinical use.

The main purpose of this chapter will be to examine critically the experimental designs and methodology, and the conclusions drawn from cognitive and orectic investigations of brain damage. An attempt will also be made to salvage from this mass of data and contradictory generalizations some unifying principles which may help to reduce the confusion within this area and to indicate a more fruitful approach to the problems.

Limited space does not allow a thorough review of the vast literature on this topic; objective experimental psychological test-findings on human material will be mainly considered here. Studies reported on single cases will be given little consideration because only limited generalizations can be drawn from them.

Findings of animal studies will not be discussed since these are of limited value in determining cerebral functions and their localization in man; but some data of animal investigations, which have particularly important implications for human material, will be referred to. Finally, the correspondence between some neurophysiological and psychological findings and theories will be discussed.

The greatest problem in reviewing the literature pertaining to some areas of investigation is to find a plan for arranging the references. References to a wide variety of studies in relative isolation and out of temporal context, without recourse to any plan, serve little purpose other than as a catalogue. It appeared to the author that the most adequate way of discussing the references, for his purpose, would be in terms of existing theories of brain organization and functioning. Thus the emphasis will be laid on the cerebral localization of functions with which these theories deal. Functions will be referred to in terms of test performance behaviour rather than in terms of psychological abilities or traits. The former term is preferred, since the latter implies a knowledge of the factorial composition of the psychological tests used and this information is not in fact available for all the tests.

THEORIES OF BRAIN FUNCTIONING AND ORGANIZATION

Following early observations that various disturbances are related to specific sites of brain lesions, the relationship between functions and the various parts of the brain has remained a clinical and a theoretical problem. Right from the start there have been two opposing schools with regard to "localization" of "higher mental functions" or rather "faculties," since the early investigators were dominated by a faculty psychology. Thus Gall (1813, as cited in Head,

Aphasia and Kindred Disorders of Speech, pp. 1-12, 1926) argued for an extreme form of localization of the "higher mental functions." On the other hand, Flourens (1824, as cited by Boring, *A History of Experimental Psychology*, pp. 62-67, 1950) upheld the view that the higher mental functions are not dependent on any particular part of the cerebrum. Both investigators agreed that primary sensory and motor functions are relatively well localized in the brain.

Despite the vast amount of experimental research aided by greatly improved techniques and methods,

¹ This chapter is based on a paper published by the author (1957).

the main issue, originated by Gall and Flourens, has not been settled. Recent notions put forward by neurophysiologists and psychologists, although re-phrased in more sophisticated terms and supported by experimental findings, demonstrate that the original problem remains. Most of the exponents of theories of brain organization have attempted to take into consideration the findings of anatomy, neurophysiology and psychology in the development of their theories; at least they have endeavoured to avoid obvious contradictions. Thus a certain degree of correspondence can be found between the theories put forward by these disciplines. Readers interested in the detailed account of historical development of theories of brain functioning and organization may be referred to Morgan (1943) and Boring (1950).

Let us examine critically the three main theories based on neurophysiological data and then see to what extent the findings of psychological investigations of the effects of brain damage support these theories.

Associationism or Anatomical Theory

This theory gained support from early clinical findings and from the effects of stimulating the cortex electrically. Jackson (1932), studying patients suffering from focal epilepsy, and Fritsch and Hitzig (1870) and Ferrier (1873) using electrical stimulation, provided some evidence that certain parts of cerebral cortex along the precentral gyrus are associated with specific types of behaviour. Also Cushing (1909) produced similar patterns of functioning by stimulating electrically the post-central gyrus.

Partly on the basis of the above evidence and partly from studies of aphasic patients, Henshen (1920, 1922, as cited in Weisenburg and McBride, *Aphasia: a Clinical and Psychological Study*, pp. 29-31, 1935) and Kleist (1934, in op. cit., pp. 31-33) argued for a strict localization of function. Henshen presented evidence to show the exact location of the specific cells "endowed by nature" with the property of receiving specific impressions. Nielsen (1946) is the modern exponent of this theory. Corresponding to this view one finds the so-called molecular or switch-board theories in neurophysiology purporting to describe the mode of cortical activity. This model draws its analogy from an elaborate kind of telephone exchange with precise connexions. The exponents of this theory concern themselves with changes occurring in neurons during the process of learning, and they have a common premise that learning merely consists in the laying down of new pathways in the nervous system, between cells in the sensory and cells in the motor systems (Hebb, 1949).

These views have been severely criticized and are now hardly acceptable. Not only are the findings in support of this theory based on methods which have

certain limitations, but new evidence renders it untenable. As regards electrical stimulation of the cortex, Penfield and Jasper (1954) demonstrated that the areas of the precentral and post-central gyri are related to different parts of the body and these can be mapped out. Continued application of the stimulus in the precentral gyrus, however, leads to further movements being added to whatever movement was produced first. Furthermore, not only do the foci for maximum effect change with time, but the effect of stimulation is dependent on the impulses arriving from other sources. Restimulation of the "same" spot often does reproduce the same sensation or movement. Frequently, however, it may produce a different sensation or movement, or it may be found that the behaviour originally produced can be reproduced by stimulation of another spot. Again, stimulation of the "same" spot which produces extension of the forearm, may produce flexion if the forearm is extended when restimulation of the "same" spot occurs. The stimulation technique confirmed these findings in the temporal and occipital areas of the cortex (Penfield and Jasper, 1954). Pampiglione and Falconer (1956) reported that clinical and electrographic features varied considerably from one point to another and even in the same patient for similar parameters of stimulation of the temporal cortex.

There is considerable evidence to indicate that the clear-cut demarcation between cortical sensory and motor areas can no longer be maintained. Twenty per cent of the stimulation experiments on the post-central gyrus result in movement rather than body sensation. Sensory representation in the motor cortex has been demonstrated (Malis, Pribram and Kreuger, 1953) and some findings suggest that each small area of the cortex is sensorimotor, with a preponderance of one or the other function (Lilly, Hughes and Galkin, 1956).

Electrical stimulation technique has been criticized for its considerable limitation as a method of investigating the localization of functions. First of all it produces some effects in so-called "excitable" areas, i.e. primary sensory and motor areas, and in the temporal lobes, but has no effects in the cortex, which lies anteriorly to the precentral gyrus and in the parietal cortex posterior to the post-central gyrus (Penfield and Rasmussen, 1950). Thus, the findings of the stimulation technique have been applied mainly to simple sensory and motor functions and it is impossible to generalize from these to the higher mental functions.

Secondly, such stimuli are essentially artificial (Mettler, 1949b; Fulton, 1947). Fulton pointed out that one cannot stimulate a single "spot" of the cortex without affecting other spots. Such stimulation is bound to affect some "simultaneous units," which

generally discharge in definite temporal sequence: "One cannot excite a single muscle through cortical stimulation without affecting other—usually antagonistic—muscles groups" (Fulton, 1947, p. 274). Patterns of movements rather than isolated responses are usually evoked. Zeigler (1957), discussing problem of electrophysiological methodology pointed out that electrical stimulation presents various problems. Neural tissue is extremely sensitive to variations in the parameters of electrical stimulation, i.e. changes in frequency, intensity, duration, or wave-form may produce markedly different responses. The site of the stimulating electrode is not necessarily identical with the site of action of the stimulus current. Variations in impedance, threshold, and patterns of response to stimulation of chronic preparations, are frequent. Continued stimulation results in an injurious effect upon neural tissue. Characteristics of electrical stimulation are not necessarily equivalent to normal, physiological excitation of nerve fibres. These factors impose considerable limitations on the functional interpretations of results based on the electrical stimulation technique alone. It should be realized also that the application of this technique to the diseased brains of conscious human beings imposes even greater limitations on the interpretation of results.

It has been pointed out with regard to studies of aphasic patients, that Kleist's and Henschen's work was inadequate since the lesions in the brains of their subjects were not delimited so precisely as to justify the conclusions of neat relationships between lesions and speech dysfunctions; in addition, the examinations described were not sufficient to show the important characteristics of language and behaviour (Weisenburg and McBride, 1935). Not only do functional deficits produced by similar lesions show great individual variations, but Conrad (1954) also demonstrated, using two hundred and sixteen subjects with aphasic symptoms whose lesions were more satisfactorily localized, that damaged areas causing different types of aphasia are widely scattered over the dominant hemisphere and do not correspond to a strictly departmental or anatomistic view.

The findings of electrical stimulation of excitable areas of the cortex and naturally and artificially induced lesions in the sensory and motor cortex show that, while in a limited sense certain small parts of the cortex may be associated with specific types of behaviour, there is lability or plasticity inherent in cerebral tissue that prevents the attempt to localize functions at specific points. Denny-Brown (1950, p. 43), analysing motor dysfunctions resulting from cerebral lesions, concluded that many areas of the cerebral cortex are concerned with motor functions, and that the precentral gyrus has relative, not absolute, importance to all movements. Even though destruc-

tion of the precentral gyrus in man has a deleterious effect on movement of limbs of the opposite side, the loss is not absolute. He pointed out: "There is thus no 'centre' for spasticity, rigidity or involuntary movements nor may a pathway be expected for these functions. Each is the outcome of partial or complete release of a normal component in movement from its natural competitor."

A number of psychological studies on patients with naturally and artificially induced lesions, in "silent" parts of the cortex, provide additional evidence (to be presented later) that the anatomistic theory is untenable.

Lashley (1930, 1952) criticized the switchboard theory from a neurophysiological and psychological point of view. He was dissatisfied with the anatomistic theory since it did not account for certain properties of cortical activity, i.e. cortical integration (to be discussed later). Recent developments in neurophysiology also indicate that the molecular, telephone exchange theories of brain functioning are no longer acceptable (Lindsley, 1956). Hebb (1949, p. 41) points out that no one now believes that direct connexions are acquired between individual cells. The conception of gradients of neural activity, in the constantly active brain, has now been firmly accepted: "The question remaining is whether gradients and fields are the only mechanisms of selective neural actions or whether they are combined with an equally important mechanism of connexions and specialized conducting paths."

Field Theory or Theory of Equipotentiality

Over-reaction against the theory of neural connexions came from Gestalt psychologists (Koffka, 1935; Köhler, 1929, 1940) and Lashley (1930, 1938). The criticism was advanced against the old theory of linear, sensorimotor connexions, in which a single cell was held to be capable of exciting a second cell with which it was synapsed. The criticism of the Gestaltists was mainly based on the facts of perceptual generalization. Animals and human beings react in a specific manner to a range of objects that have only certain general or relational characteristics in common, and this reaction cannot be regarded as the result of the stimulation of identical nervous elements. A square is seen as a square, whatever its size, and in almost any setting; looking at it, fixation varies continuously, but we remain aware only of the single object. These undisputed facts of behaviour have been interpreted as suggesting that perception is independent of the *locus* of excitation.

Lashley (1929) presented other forms of evidence which make it difficult to accept the idea of a structural trace as the basis of memory. For example, removals of parts of the rat's cerebral cortex do not

affect habits selectively. He concluded that the degree of impairment of maze learning and retention of such habits was proportional to the extent of cortical surface destruction (mass action) and unrelated to the *locus* of the damage (equipotentiality). According to him, all cells in a system acquire the same functions and distinct learning processes are not necessary for habits involving different stimuli or different parts of a cortical field.✓

On the basis of the above evidence, Lashley argued that all neurons of the cortex must be in constant activity and the integration must comprise complex patterns of interaction. He discarded the idea of conduction over relatively isolated paths (Lashley, 1942).

Köhler's position is similar to that of Lashley. In order to account for perceptual generalization, he postulated electrical fields in the cortex (Köhler, 1940; Köhler and Wallach, 1944). This is an alternative idea to Lashley's notion of irradiating waves of excitation and their interference patterns. Pavlov (1927) and Hull (1943) accepted the notion of a field action (irradiation and concentration, and the notions of gradients respectively), but did not specify the way in which perceptual generalization occurs.

✓Köhler and Lashley agree in their stress on patterning in the central nervous system as against *locus* of excitation, hence their doctrines are referred to as theories of equipotentiality. (Köhler does not use the term). The problem of patterning and form has been studied mainly in visual perception; it is only assumed that perception in other sense modes depends on the same principles. The law of equipotentiality generally holds that within functional areas of the cortex, the cortical cells are equipotential. Thus, the cortex does not function entirely in a unitary fashion, but the principle of mass action and equipotentiality, in effect, minimizes the role of so-called "trophic centers" in the cortex as organizers of behaviour.✓Lashley (1929) adopted an extreme position with regard to equipotentiality in the field of problem-solving and retention. Following an extensive series of experiments on maze learning and retention in rats, he concluded that any part of the rat's cortex is as good as another in its contribution to problem-solving of this sort. This view rests on the assumption that the sensory projection-areas have no critical sensory function in the maze running. (He adduced some evidence that the visual area of the cortex has an important non-visual function in retention of the maze habit (Lashley, 1931).)✓Maze running, he argued, is directed solely by some central nervous mechanism, and the various parts of the cortex are equipotential in their contribution to this central mechanism.✓Lashley's work continues to exercise considerable influence due to the extrapolated hypothesis that the human brain also

works in a unitary fashion, despite the fact that Lashley himself modified this view (Lashley, 1933).

The above findings initiated a considerable amount of theorizing about generalized effects of brain damage.

Köhler and Wallach (1944) have proposed a new treatment of perception which attempts to deal with certain obstacles for field theory (anatomical distortion of the cortical retina, see Hebb, 1949, pp. 51-58).

✓The observed phenomenon of so-called figural after-effect showed that constant stimulation of parts of certain sensory surfaces of the retina sets up states of "fatigue" in corresponding areas of cortex which have measurable effects on the perception of stimuli projected subsequently on to the same region. These effects include fading of colour, apparent increase of distance from the observer, and displacement effects. Köhler and Wallach propose that the flow of electric currents in the cortex, aroused by visual excitation, increases the resistance of the quasihomogeneous volume of the tissue through which they flow. This increased resistance, which they call satiation, changes the course of current flow, which in turn results in the observed figural after-effects. Köhler and Fishback (1950) suggest that the injured tissue of brain-damaged patients may be regarded as comparable to a highly satiated part of normal tissue; that this area is polarized by the currents of test objects and that, as a consequence, such objects recede from the place of the defect as reported by Bender and Teuber (1947).

✓Klein and Krech (1952) reported that the brain-injured show greater figural after-effects than those whose brains are not injured.✓They used the kin-aesthetic test as a measure of figural after-effects. They drew a parallel between brain damage and satiation as produced by continuous stimulation.✓A suggestion was made by them that whereas satiation results in temporary and localized reduction of conductivity, brain injury produces a permanent and generalized state of lower conductivity. They pointed out that the properties of figural after-effects measure this conductivity so that the rate of appearance, extent and persistence of figural after-effects would be greater in brain-damaged cases than in normals.✓

A similar theory has been put forward by Shapiro (1951a, 1952, 1953, 1954a, 1954b). Using a model derived from Pavlov, and basing himself on the negative induction phenomena observed by Pavlov, he developed a theory exclusive to brain damage.

✓According to this theory, brain-damaged subjects suffer from exaggerated inhibitory effects, and identical effects are produced by continuous stimulation. Excitation of one part of the brain by a sensory surface leads to the inhibition of other parts, and excitation of one stimulus-response sequence results in the inhibition of other stimulus-response sequences.✓He tested

this theory on brain-injured and non-brain-injured patients, demonstrating that negative induction phenomena are more pronounced in the former than in the latter.

✓Eysenck (1955a, 1955b) identified *satiation* with Hull's concept of *reactive inhibition* (Hull, 1943). According to Eysenck's theory, in the sphere of personality, subjects, in whom strong reactive inhibition is generated rapidly and dissipated slowly, develop hysterical types of disorders in neurotic breakdown; conversely, individuals in whom weak reactive inhibition develops slowly and dissipates quickly, are predisposed to develop dysthymic disorders. ✓Clinical evidence indicates that the pattern of symptoms of the hysteric is similar in many respects to the pattern of symptoms of the brain-injured person. ✓Petrie (1952a) provided some evidence that brain injury (surgical interference by frontal leucotomy) produces a marked shift in the direction of greater extraversion as measured by objective tests. This finding, Eysenck argues, is in agreement with the hypothesis that brain injury produces an increase in speed and strength of reactive inhibition as a concomitant of the measured increase in extraversion. He pointed out that Reese's *et al.* (1953) findings on conditionability and Klein and Krech's (1952) results on kinaesthetic figural after-effects support his theory. ✓The former investigation demonstrated that brain-injured patients are inferior in conditionability to non-brain-damaged subjects; the latter showed brain-damaged individuals to manifest greater figural after-effects than non-brain-damaged subjects.

The three notions, i.e. satiation, inhibition produced by negative induction and reactive inhibition, appear to have much in common. They all imply that a continuous excitation of a sensory surface leads to some kind of process in the cortex which causes subsequent responses to the same excitations to be altered. These alterations are much more pronounced in the brain-damaged than in the normal individual. Unfortunately, there is, at the moment, no direct neurophysiological or psychological experimental evidence regarding the identity or lack of identity of these notions. Thus, it would be premature to claim that the results reported in support of any one of these theories support another. Satiation rests on assumptions concerning processes in the central nervous system, i.e. polarization of cortical tissue by electrical currents; inhibition by negative induction assumes such cortical processes as irradiation and concentration of excitation and inhibition, as well as their mutual induction. Both notions imply spatial and temporal orderings of experience which correspond to spatial and temporal orderings of physiological processes. In Köhler's theory (1940, 1944) these orderings are predicted on the principle of "isomorphism," which,

apart from anything else, holds that a consciously perceived square must be paralleled by a corresponding squarelike excitation pattern at some place in the visual brain. Pavlov (1927) talks about *analysers* which denote the part of the nervous system dealing with a definite kind of stimuli. Reactive inhibition, on the other hand, does not rest on any processes in the cerebral nervous system and merely implies a temporal aspect of its functioning.

Goldstein (1939) developed a theory to account for the effects of brain damage which is based mainly on Gestalt psychology. He criticized localization theories based on symptomatological considerations. According to him—

✓Localization of performance no longer means to us an excitation in a certain place, but a dynamic process which occurs in the entire nervous system, even in the whole organism, and which has a definite configuration for each performance. ✓This excitation configuration has, in a certain locality, a specific formation ("elevation") corresponding to the figural process. This "elevation" finds its expression in the figure produced in the performance. A specific location is characterized by the influence which a particular structure of that area exerts on the total process, i.e., by the contribution which the excitation of that area, by virtue of its structure, makes on the total process (Goldstein, *The Organism*, pp. 260-261, 1939).

He reached the same conclusion with regard to the localization of sensory qualities. ✓A perception is a specific pattern of the whole organism (Goldstein, *op. cit.*, p. 268). In brain-damaged patients, certain cortical areas, through lesions, are isolated from the background of the rest of the central nervous system. ("Isolation" barriers can also be produced "functionally.") When such isolated areas are stimulated, they yield abnormal responses. ✓The responses may be exaggerated and of abnormal duration. They may be primitive (less complex than normal), easily distracted, or there may be no response. Symptoms shown by brain-damaged patients can be easily understood in terms of these abnormal responses produced by isolation. ✓The most important aspect of isolation for Goldstein is rigidity. Secondary rigidity, as distinguished from primary rigidity due to functional isolation, is regarded as being due to organic isolation and is dependent on the impairment of the higher mental processes, i.e. intelligence or abstraction (Goldstein believes that defective intelligence and defective abstraction-concreteness themselves are caused by organic isolation.) ✓Brain-damaged patients exhibiting secondary rigidity are not rigid when they understand how to do the task. However, when they are forced to do a task they are unable to cope with by reason of their reduced capacity for abstraction (lack of intelligence), they become rigid. Their reaction to a problem

which they cannot solve is to do something which they are able to do. Such rigid performance continues even though it is inadequate and they cannot shift even if asked to do so. Apart from that, these patients display concreteness which is to be regarded essentially as an inability to abstract (due to isolation). ✓

Goldstein and Sheerer (1941), in a monograph on concrete behaviour, introduce a number of tests for concreteness. These tests generally require the subject to make an abstraction by sorting objects and explaining the principle of sorting, and then to shift to a different method of sorting, which requires a different principle of abstraction. It should be pointed out that the authors seem to lose sight of the previously made distinction between primary rigidity, secondary rigidity and concreteness. Concreteness means now an inability to abstract and an inability to shift.

✓ Goldstein (1948) also concluded from the observations of aphasic patients with tumours that aphasia is associated with impairment of the attitude towards the abstract and categorical. This personality change is to be found especially in cases of lesions of the frontal lobes, but it may result to some extent in cases of lesions of other parts of the cortex. The author also maintained that this change is present to a greater degree in patients with lesions in the left hemisphere than with lesions in the right hemisphere.

Those workers, who may be called proponents of a "unitary" theory of brain functioning, still may be shown to differ somewhat in their conception of the effects of brain damage. The unitary nature of the process they discuss may in fact be shown to refer to two aspects of functioning which may, or may not, be related. In the first place, there are those who consider the effects of brain damage to be general *whatever* the actual site of the lesion. For example, Goldstein discusses concreteness due to organic isolation, Klein and Krech talk about lowered cortical conductivity due to satiation, Shapiro speaks of exaggerated inhibition produced by negative induction, Eysenck merely refers to increased reactive inhibition; Lashley takes a similar view with regard to maze learning in the rat. On the other hand, Köhler, for example, argues for generality of the kind of effect (increased satiation in areas adjoining pathological focus) but nevertheless such a theory lays emphasis on the actual situation of the damage. Pavlov (Shapiro based his theory on Pavlov's model) is concerned with the importance of analysers in behaviour. Lashley postulates a limited equipotentiality within functional regions for functions other than maze learning.

These theorists therefore may be labelled unitary theorists in so far as they emphasize mainly the general and generalized processes which result from brain injury and tend to play down the specific effects dependent on the site of the lesions. None of these

workers, with the exception of Lashley, has in fact tested his theory systematically in different sense modalities. ✓

Let us see now to what extent the existing factual data support the above views. No specific attempt will be made to evaluate the theories from the viewpoint of data drawn from contemporary physiology of the central nervous system. Firstly, this is not within the scope of this chapter, and secondly, it is not all that important, since the above theories can be accepted as working hypotheses capable of explaining and systematizing the existing data derived from the behaviour of organisms and as such need not wait upon direct neurological confirmation.

✓ Lashley's theory accounts in a general way for much of the behaviour and it does not conflict with the results of histological studies, nor does it contradict any physiological findings (Sholl, 1956). Like Kohler's theory, however, it does not account satisfactorily for learning and memory processes. Both theories stress the point that the pattern or shape of the sensory excitation determines learning and memory, and not the *locus* of stimulation. Such a position opposes the idea of the memory trace being a structural localized modification of the neurons. It is hard to see how Köhler and Lashley's dynamic reverberatory neuronal circuits could be stable enough to maintain memory indefinitely without becoming disorganized (Hebb, 1949, pp. 10-11; Sholl, 1956, p. 88). ✓ The fact that the cortex can be traumatized by concussion, epileptic seizure, or electroconvulsive therapy without having detectable effects on earlier memories strongly suggests that the repetition of a reverberatory activity tends to induce some lasting structural modification. ✓

Lashley's principle of equipotentiality and mass action was developed from an extensive series of experiments on maze learning in rats. First of all there are some theoretical difficulties with this view as applied to human beings. ✓ The findings of animal studies are of little value in determining cerebral functions and their localization in man, because of the general trends of neural development towards encephalization. In lower animals the higher cortical centres display more generalized functions; and, as they gradually evolve phylogenetically from a relatively undifferentiated structure of tissue (pallium), they become gradually structurally differentiated, more complex and increasingly specialized with regard to functions which they take over from lower centres (Morgan, 1943). ✓ The advent of such higher intellectual functions as speech in human beings has resulted in a different organization of tracts in the central nervous system (Dandy, 1933). Osgood 1953, pp. 474-494, in his survey of neural functions in learning, concluded that with regard to maze learning

in the rat there is evidence for localization of "higher functions" within the cortex and for Lashley's principles; however, these findings were derived from complex learning tasks performed by rats whose cortical structures are relatively undifferentiated. ✓ Performances similar to maze learning, after extirpation has been effected, have not been systematically investigated in monkeys and human beings; nevertheless the anatomical and neurophysiological evidence for the principle of encephalization strongly suggests that Lashley's model of brain functioning and organization is very unlikely to apply to human beings. ✓

✓ Hunter (1930) criticized Lashley's view on the ground that the maze learning had not been proven to be independent of sensory control. According to him, some evidence suggests that all sensory modalities contribute about equally to the control of maze performance and it is very likely that a lesion in any sensory projection area of the cortex would produce about the same deficit in sensory function, giving the appearance of equipotentiality. ✓ Pickett (1952) quotes additional experimental studies on rats to support this view and he himself tested Lashley's theory of equipotentiality by using a maze which can be run only on the basis of tactual and kinaesthetic cues. The results of the latter study are not consistent with the theory of equipotential function. Lansdell (1953), using a new type of intelligence test and rats reared in a complex environment, studied the effects of variously localized lesions; the results are regarded as inconsistent with the equipotentiality hypothesis.

✓ As regards the human material, no direct systematic experimental work has been done to test Lashley's principles, since it is not possible to submit human subjects to direct experimental investigations, as it is the lower animals, and clinical material does not provide cases for crucial experiments. ✓ Several studies quoted by McFie and Piercy (1952) are in agreement with their own findings, and with other studies (Battersby, Krieger, and Bender, 1955; Zangwill, 1946), supporting Lashley's notion that retention and learning are functions of the brain as a whole. However, this evidence cannot be regarded as conclusive. Firstly, no study has been found which has investigated thoroughly and systematically learning and retentive abilities in a brain-damaged population, using the visual, auditory and tactual modalities, various materials and different modes of reproduction. Secondly, Ghent *et al.* (1955b) demonstrated that an impairment of a tactual learning discrimination was confined to the side opposite the lesion; these data emphasize the importance for some learning of that hemisphere which receives the main projections from the stimulated surface. Thirdly, the present author

(1956, 1959) showed that excisions of different parts of the brain may have different effects on learning ability tested in the three sense modalities using recall and recognition. ✓

Apart from the above, the theory can be criticized on more general grounds. ✓ The formulation of the laws of cortical organization is difficult to test. The mass-action principle implies a positive correlation between behaviour and amount of tissue destroyed; the results obtained from one form of behaviour do not necessarily apply to the results of other forms of behaviour. Learning and retentive abilities are only two aspects of higher mental activity which are not necessarily highly correlated with other mental abilities such as general intelligence. ✓ Spearman (1932) and Thurstone and Thurstone (1941) regarded retention as a different process from intelligence, owing to low correlations obtained between it and other intelligence tests. (Lashley was aware of these limitations.)

The literature on human beings with brain damage has on the whole failed to substantiate the principle of mass action in general and even within limited functional regions, but some positive evidence has been presented. ✓ Halstead and Shure (1954) reported results which, in their opinion, indicate substantial confirmation of the principle of mass action. It is impossible to evaluate their statements because of insufficiency of data reported. ✓ The correlations between disturbance of the "abstraction factor" and the mass of frontal lobe tissue removed, and between the "power factor" and non-frontal areas are high. However, the correlation between the abstraction factor and non-frontal areas is reported to drop to 0.20; one would require a sample of about a hundred cases to make this value significant at the 5 per cent level. Apart from that, the authors pointed out that the various cortical areas are of "decidedly unequal importance for the mediation of various intellectual functions." Further evidence against the principle of mass action for various functions has been presented by many investigators (Hebb, 1942; Klebanoff, 1945; Landis, Zubin and Mettler, 1950; Zubin, 1952; Meyer, 1959).

The evidence for the equipotentiality principle provided by the studies quoted above (Ghent *et al.*, 1955b; Meyer, 1956, 1957b) argues strongly against the extreme form of equipotentiality for learning ability in man. A considerable amount of evidence will be presented later which does not support Lashley's extreme form of equipotentiality for other functions. Even Lashley's modified view, i.e. equipotentiality of cortical cells within an anatomical region, is not consistent with some known facts (Hebb, 1949, pp. 38-54).

✓ The main reason why Lashley's laws of cortical organization have, on the whole, found little support

from experimental investigations is that, as stated, they lack precision and therefore are difficult to test. It may be that these principles hold under restricted conditions which must be rigidly defined.

Köhler's theory has been criticized on empirical and phenomenological grounds. Osgood (1953, pp. 236-243) pointed out that it is difficult to understand how Köhler's non-neural electrical currents, which seem to flow without regard to anatomy, can eventuate in behaviour. "At some point along the line we must transfer from direct currents in a field to impulses in nerve, since this is the way muscles are innervated" (op. cit., p. 237). He also disagreed with Köhler's emphasis upon figural after-effects which require, according to Köhler, a field theory for their understanding. These after-effects can be explained on the basis of known neurological mechanisms of the visual projection system and the postulation of a novel set of non-neural electrical forces in the brain is superfluous. Osgood and Heyer (1952) advanced an alternative explanation of figural after-effects in terms of satiation. Hebb (1949, pp. 58-59), following a critical examination of field theory and equipotentiality, concluded that there is no way of dealing with attention and attitude in terms of the configurational hypothesis and that it leaves too little room for the factor of experience. He also argued that some phenomena (displacement effects) seem inconsistent with the theory of figural after-effects and contended that the theory does not dispose of the difficulty related to the anatomical distortions of the cortical retina. Lashley *et al.* (1951) attempted to test the electrical field theory by placing a grid of strips of gold foil in contact with the visual cortex and by thrusting gold pins through the cortex in the macular area of monkeys. A variety of tests failed to reveal any disturbances of visual function resulting from either of these procedures. Similar findings were obtained more recently (Sperry and Miner, 1955; Sperry, Miner and Myers, 1955). These findings throw considerable doubt on the importance of the action of electric currents in cerebral integration as postulated by field theory. It must be remembered that there is no evidence that *cortical fields* were disrupted by the methods used in these studies. Howarth (1957) obtained some results which are contrary to the hypothesis of Köhler and Wallach; Seagram (1957) concluded, on the basis of experimental results, that the whole topic of figural after-effects is more complex than has been assumed. Brenner (1953) reported findings which, according to her, are contrary to the conclusions of Deatherage and Bitterman (1952) and are inconsistent with the satiation hypothesis as an explanatory model. The latter workers reported that continuous visual stimulation in the path of movement altered the threshold and the nature of the apparent

movement perceived, which findings they cite as evidence for satiation hypothesis. Brenner, on the other hand, demonstrated that all forms of continuous stimulation have an identical effect on the perception of apparent movement; thus, an explanation which depends on a direct isomorphic relation between perception and cortical events is not tenable.

The methodological differences in various experiments testing Köhler's theory make it difficult to draw more than tentative conclusions. It would appear on the whole that the results fail to support the theory entirely and additional crucial experiments are needed to clarify the equivocal results obtained in these investigations.

The available evidence for the theories of brain damage, based on the hypothesis that brain damage is analogous to satiation, is, on the whole, equivocal and these theories are not fully acceptable. Here again, differences in experimental designs may account for the inconsistencies in the findings. Jaffe (1954) failed to confirm the results reported by Klein and Krech (1952); not only did brain-damaged subjects not differ from normals in the amount and persistence of kinaesthetic figural after-effects, but also these after-effects were not greater for the damaged hemisphere when compared with the undamaged one. This latter finding is particularly damaging to the theory of lowered conductivity in brain damage postulated by Klein and Krech. The author argued that his results are incompatible with the hypothesis of Köhler and Wallach.

Additional evidence on the perception of apparent movement makes it difficult to consider satiation as an analogue of brain damage. Brenner (1953, 1956) reported that in the perception of apparent movement the effects of brain damage and those of satiation are quite dissimilar. Continuous stimulation in four modalities resulted in a significant restriction of the range of time intervals over which apparent movement is perceived by normal subjects. Brain-damaged subjects did not differ markedly from normals in lower threshold values. The upper threshold was higher for the brain-damaged group than for normals. Brenner argued that the latter finding is in the opposite direction to that predicted on the basis of Shapiro's theory (1954b) and to that predictable from the theory of Klein and Krech (1952). She also demonstrated that after eight measurements of the thresholds there was no indication of a decrease in optimal time for apparent movement in brain-damaged subjects, such as might be expected on the basis of Eysenck's theory (1955a, 1955b). Teuber and Bender (1950), reported findings which are incompatible with the notion of isomorphism and the theories of brain damage based on a satiation hypothesis. The perception of apparent motion was obtained from patients

with penetrating wounds in the visual cortex; thresholds of apparent movement were not significantly different under conditions where perception of apparent motion was obtained across a scotoma, nor under conditions where it was obtained in intact regions of the field. It should be pointed out that the above experiments are not crucial tests of the theories; they do, however, throw a considerable doubt on the validity of these theories.

Shapiro's theory of brain damage deserves to receive special consideration since several of the deductions derived from this theory in the field of visual perception were thoroughly and systematically tested and various relevant factors were put under control (Shapiro, 1951*a*, 1952, 1953, 1954*a*, 1954*b*). On the whole, the theory was supported by experimental findings and an independent verification of these findings was reported (Williams *et al.*, 1956). The theory, however, has not been tested in other than visual modalities and the support for it was adduced on the basis of statistical significance of mean differences obtained between organics and non-organics; many brain-damaged patients did not behave as predicted from the theory. The other weakness of this theory is that it is based on a Pavlovian model of brain functioning. Konorski (1948, pp. 34-60), in his excellent critical evaluation of Pavlov's theory, pointed out that the whole style of this theory is foreign to contemporary physiological thought concerning the nervous system. What is more important, such concepts as excitation, inhibition, negative and positive induction are vaguely defined, the theory contains intrinsic contradictions and its statements are not in harmony with the experimental facts on which they are based.

Unless Shapiro's theory is tested further, using different modalities, and unless other relevant factors are incorporated in it and their relationship clarified, it cannot be fully accepted.

Goldstein's theory and his tests of concreteness have been criticized on general grounds. Hebb (1945) rightly pointed out that the theory is too broad and ill-defined to be meaningful, and is likely to lead to an *ad hoc* interpretation of symptoms. It explains at once too much and too little. Behaviour that seems to involve abstraction is called concrete and vice versa. The fact that amnesic aphasia (Goldstein, 1936) and schizophrenia (Balles and Goldstein, 1938) can be reduced to a "loss of the abstract attitude" demonstrates the vagueness and inconclusiveness of the term.

There has been no agreement concerning what Goldstein's tests measure. They generally require abstractions to be made by sorting objects and explaining the principle of sorting, and then to shift to a different method of sorting which requires a

different principle of abstraction. It will be remembered that Goldstein and Sheerer (1941) did not maintain the original distinction between concreteness and secondary rigidity (Goldstein, 1939). "Abnormal concreteness" as "measured" by the tests seems to cover both inability to "abstract" and inability to "shift." Also, the tests seem to involve both sorts of rigidity, i.e. primary and secondary. Payne (1954) argued that Goldstein did not provide a proof for his assumption that the tests do measure concreteness, since he did not intercorrelate them. Thus, there is no reason to believe that they do have very much in common besides intelligence. Apart from that, he did not show that these tests measure anything more than general intelligence; if intelligence could account for a good deal of the test variance, the failure to do the test correctly would not necessarily indicate organic "isolation." Finally, the tests are qualitative and Goldstein did not standardize them on a normal population; he merely assumed that people of normal intelligence would be able to do them correctly. His emphasis on extensive studies of individual patients, without control data, affords no statistical information evaluable by standard methods, and lends itself to overgeneralization.

Goldstein's theory stimulated a great deal of investigation, the greater part of which attempted to discover whether or not Goldstein and Sheerer's tests discriminate between brain-damaged and non-brain-damaged subjects. Werner and Strauss (Werner, 1946; Werner and Strauss, 1940-41; Strauss and Werner, 1942-43*a*, 1942-43*b*) performed experiments into Goldstein's theory of isolation, comparing a number of brain-damaged children and a control group of non-brain-damaged children of the same intelligence; several differences, all postulated by Goldstein, were found. Many studies (Rylander, 1939; Halstead, 1940; Tooth, 1947; Lidz, Gay and Tietze, 1942; Sheerer, 1949; Grassi, 1953; Battersby, Krieger, Pollack and Bender, 1953) produced results, which, to some extent, support Goldstein's claims demonstrating that various tests of abstraction and shifting discriminate between brain-damaged subjects and various groups of non-organic individuals. However, none of these findings may be considered as conclusive, since either intelligence was not controlled, or neurotics and psychotics were not included. Boyd (1949) and Tooth (1947) demonstrated a strong relationship between the ability to do some of the tests used in the above studies and intelligence. The latter author showed that, when his brain-damaged and non-brain-damaged groups were matched for intelligence on Koh's block test, the test did not differentiate the groups significantly. Also, some evidence is available indicating that neurotics may perform as poorly as organics (Tooth, 1947) and psychotics may

do even worse than brain-damaged patients (Boyd, 1949). Further studies failed to support Goldstein's theory. Armitage (1946) concluded that the Block Design Test cannot be used as a screening device between brain-damaged and non-brain-damaged subjects. Weisenburg and McBride (1935) opposed Goldstein's view because their cases showed no evidence, so far as the test findings were concerned, for assuming such fundamental, universal disturbance as Goldstein described. Meyers (1947) found that aphasic patients perform as well as their matched controls on non-verbal tests of inductive reasoning. McFie and Piercy (1952a, 1952b) reported that results obtained from testing patients with localized cerebral lesions on Weigl's Sorting Test do not support Goldstein's view that an impairment of abstraction results from a lesion irrespective of its location; neither do their results confirm the view that dysphasia is contingent upon impairment of abstraction. Brown (1955) showed that no significant difference in abstracting ability, as measured by Goldstein and Sheerer's tests, was found to exist between dysphasic patients and normal controls. Bauer and Becka (1954) demonstrated that aphasic patients did not show greater impairment of abstract ability than other brain-damaged cases and many of the aphasics displayed highly abstract behaviour. The results of the above studies, incomplete as they are, throw considerable doubt on the validity of Goldstein's theory. Research suggests that, while the ability to abstract may be impaired in some brain-damaged patients, there is no conclusive evidence that rigidity, as measured by Goldstein's tests, is produced by brain damage. There is, in fact, no clear evidence that the ability to abstract is anything more than general intelligence. Insufficient research has been performed to permit a clear-cut conclusion.

It is relevant to say a word about the work of Bender and Teuber (1949), since they indicated directions in which to search for a theory of brain functioning in the visual sphere, and these suggestions have been frequently taken at their face value as being applicable to the "unitary" theory of brain functioning. Describing various disturbances in visual perception following cerebral lesions, they drew attention to the following phenomena: on the one hand, it is known that circumscribed injuries in the visual cortex produce predictable regional losses of function in the field of vision; there is an approximate point-to-point correspondence between localized lesions in the structure and localized losses in function; on the other there is also evidence of generalized alteration of functions in those parts of the field where vision is unimpaired. Such radical alterations in the mode of visual functioning as fluctuation, obscuration, extinction, completion, and changes in perception of shapes,

spatial organization, flicker fusion, real and apparent motion have been reported.

It is sufficient to point out that all these alterations in function were observed in patients with posterior lesions (particularly occipital) performing on simple tasks involving visual perception, and that the phenomena reported may not be found in cases with lesions elsewhere. To take one phenomenon, i.e. C.F.F. (critical flicker frequency), Battersby (1951), Battersby, Bender and Teuber (1951) and Medina (1957) reported that under their experimental conditions, there was no alteration of the C.F.F. in patients with frontal lesions. The first two studies confirmed findings of other investigations that C.F.F. is decreased in patients with posterior lesions.

It should be pointed out that Teuber himself (1950) expressed the view that at the present stage of knowledge neither the assumption of regional localization of functions nor the postulation of a general factor are foregone conclusions. According to him, multifactor and general-factor hypotheses should be used only as a guiding frame of reference for the design of new tests and experiments which may lead to negative as well as positive evidence for either view.

Finally, it is pertinent to discuss briefly tests of brain damage, since designers of these assume explicitly or implicitly some generalized effects of brain injuries (unitary view) without taking into consideration the nature or the *locus* of lesions. A number of such generalized effects have been utilized, e.g. the already mentioned ability to abstract, learning and retention, perceptual abilities and intellectual deterioration (mental deterioration index). The reader interested in various tests of brain damage may be referred to Yates (1954, 1956), who described them and discussed their validity.

One of the greatest weaknesses of these tests is the lack of clear theory exclusive to brain damage behind them. Apart from this, most of them contain serious flaws and lack the basic requirements of a valid study. In addition, misclassifications reported are high and, frequently, claims of low misclassification are negated by cross-validation studies.

It appears that most investigators have been mainly concerned in developing tests which discriminate organics from non-organics at a high level of confidence, forgetting that despite high statistical significance of mean differences obtained, misclassification may still be too high for such tests to be sensitive enough for clinical use. Apart from that, alternative hypotheses are rarely considered and very seldom is any effort made to investigate why some brain-damaged patients do not behave as predicted. The evidence available from these studies can hardly be taken as a crucial proof for a unitary theory of brain damage.

✓It may be seen from the foregoing that none of the existing field theories of brain organization and functioning has been conclusively supported by the experimental evidence. Those theories which postulate an impairment of some cognitive ability, irrespective of the *locus* of the damage, are untenable. Those theories which postulate some general factor underlying various cognitive impairments have not been precisely stated nor adequately investigated to be acceptable in their existing forms. ✓

Theory of Regional Equipotentiality or Functional Equivalence

✓This theory is intermediate between the two extreme ones which have been presented above. It argues for a limited form of localization. Weisenburg *et al.* (1936, p. 129), concluded that: "There are in all probability more or less independent groups of mental abilities. The typical normal adult does not show great differences in the development of these abilities . . . In cases of brain disease, however, or at least in cases of localized brain disease, they may be affected unequally." Lashley, as it has been pointed out, modified his own earlier theory and expounded the view of regional equipotentiality or "functional equivalence of parts within specific areas" (Lashley, 1933).

✓The so-called molar theories of connexionism in neurophysiology correspond more or less to the above view. Strictly speaking these theories are neither molar nor molecular. Like the molar, they are mainly concerned with the construction of general models describing neural activity in the learning process; however, they are connexionistic inasmuch as they assume that the changes occurring in learning are to be found in particular neurons and synapses and that new pathways are formed. ✓Hebb's theory of cortical activity adopts such a model (Hebb, 1949). ✓Hebb's theory of behaviour deserves special consideration since it leads to the most highly developed model that is based as far as possible on knowledge of the physiology of the central nervous system, and makes an attempt to find some correspondence between neurological and psychological conceptions. ✱

✓Hebb adopted a half-way position between field and connexionistic theories, taking advantage of some of the obvious values in each theory and avoiding the difficulties connected with them. He pointed out that Köhler and Lashley deal adequately with the problem of perceptual generalization, but that they face great difficulty in their treatment of perception, learning, attention and attitude. According to Hebb, perception is not a unitary process, immediately given, but is slowly acquired through learning (Hebb, 1949, pp. 17-37). Secondly, the theory of

innate stimulus equivalence and equipotentiality is inconsistent with some experimental evidence (*op. cit.*, pp. 38-54); for example, a learned response can be more readily elicited from one part of retina than another. Such evidence strongly argues against neural fields and gradients as the only mechanism of integration. Finally, since configuration theory requires the memory trace to be dynamic and dependent on activity in neuronal circuits, it is difficult to see how stable learning can occur and how autonomous central processes can exist and can influence behaviour (*ibid.*, pp. 12-16).

✓In order to overcome the above difficulties, Hebb made the following assumptions: (1) a particular perception depends on the excitation of particular cells at some point in the central nervous system, (2) a separate learning process is necessary for the elicitation of the same response by stimulation of a separate region in a receptor surface, (3) the persistence or repetition of a reverberatory activity ("trace" underlying unstable memory) tends to induce some kind of growth process which leads to a permanent change in the connexions of the constituent neurons and so forms a basis for more permanent memory (*ibid.*, pp. 60-66).

Impulses that arrive at a sensory area of the cortex may preserve certain topographical similarities with the pattern of stimulation, but these are soon lost among the complexities of neuronal interconnexions. A frequently repeated particular stimulation results in the slow development of a "cell-assembly" which consists of a diffuse structure of cells in the cortex, capable of acting briefly as a closed system and providing facilitation to other such systems. A series of such events constitutes a "phase sequence" which is the neural basis for thought process. The facilitation from one of these activities on the next constitutes the neural basis for "attention."

The theory is a form of connexionism; it does not, however, deal in direct connexions between afferent and efferent pathways. The connexions are merely utilized to establish autonomous central activities which eventually form the basis for further learning. The postulation of cell-assembly recognizes "a limited field action in the sensory projection areas, and something like a limited equipotentiality between cells that are in functional parallel in physiological systems" (*ibid.*, p. 40). The concept of cell-assembly deals adequately with the problem of perceptual generalization.

Hebb's theory will easily account for much of the experimental data connected with perception, perceptual generalization, and learning. It also explains satisfactorily why destruction of part of the cortex will lead to an impairment of specific functions, why intelligence as measured by standard tests often

remains unaffected following an injury to the brain (the evidence for these clinical facts will be presented in the next section of the chapter), and why some intellectual capacities are retained in old age when others are declining (Gilbert, 1935; Wechsler, 1944; Shaie *et al.*, 1953; Strother *et al.*, 1957).

Psychologists and neurosurgeons have frequently been puzzled to find intelligence level unaffected following the destruction of large parts of the human brain. Hebb (1949, pp. 294-299), analysing the nature of intelligence on clinical and theoretical grounds, draws a distinction between two components of intelligence. Intelligence *A* is an innate potential for learning, retaining and rearranging of perceptions and conceptual activities (in Hebb's theory cell-assemblies and phase sequences). It is an hypothetical concept and it refers to an innate capacity for acquisition of what is usually meant by intelligence. Intelligence *B* refers to the functioning of the brain in which development has occurred. It is related more to experience and can be recognized in everyday life and in the responses in I.Q. tests. Once a certain type of behaviour (phase sequence) has been established it does not depend on a particular amount of brain tissue and can persist when the amount available has been decreased. However, the innate capacity for elaborating and building new conceptual activities (intelligence *A*) is immediately diminished by damage to the brain. This aspect of intelligence has frequently been reported to be impaired in brain-damaged patients. A similar distinction between two components of intelligence has been drawn by Cattell (1943). His "fluid ability" refers to a "purely general ability to discriminate and perceive relations between any fundaments new or old." "Crystalized ability," on the other hand, consists of "discriminatory" habits long established in a particular field, originally through the operation of fluid ability, but no longer requiring insightful perception for their successful operation.

Both components enter into intelligence tests, but in adults the crystalized ability or intelligence *B* determines more the level of performance, whereas in childhood the fluid ability or intelligence *A* is predominant.

In support of this hypothesis Hebb (1949, pp. 289-294; 1942) and Strauss and Lehtinen (1950) provide a considerable amount of evidence showing that damage to the infant brain has much greater effect on subsequent generalized intellectual functioning than a similar damage to the adult brain. Weisenburg and McBride (1935), Rylander (1939) and Hebb (1942) support the hypothesis that brain-damaged adults (outside the speech area) are more impaired on tasks requiring logical solution of novel problems than on tasks involving problems of a familiar kind.

Meyer (1959) supported this view to some extent; he also showed, however, that certain kinds of learning of new solutions depend more on some brain regions than others. Inglis (1957) demonstrated that in elderly psychiatric patients with memory disorder, an impairment of learning ability seems to be associated with a disturbance in the solution of novel problems.

Another important aspect of Hebb's theory is the treatment of the memory trace. The activity of the cell-assembly does not depend on the maintenance of unique circuits. A trauma to the brain may leave much of the memory intact, since it has been established by process of growth and does not depend upon a dynamic reverberatory state that might be unstable.

Finally, the theory is possibly the only one that presents psychological problems in a manner which can be appreciated by the anatomist and the physiologist, and it is able to account for most of the facts as they are known today.

The acceptance of Hebb's theory demands three histological assumptions to be verified, i.e. the postulated growth process, the synchronization of activity in converging axons, and the anatomical convergence of the fibres themselves in the cell-assembly. Sholl (1956) pointed out that these assumptions are not in conflict with the facts. The histological information makes the occurrence of synchronization and convergence highly probable; the growth process, however, has not been verified. It should be pointed out that in recent years some data have been accumulated which support Hebb's notion that learning is a dual physiological process. Thus Boycott and Young (1955) showed that various ablations of parts of the brain of the octopus destroyed the capacity for permanent or long-term memory, but left immediate memory intact. Since immediate performance was normal it cannot be argued that the lesions produced defects in perception, attention, or motivation. Duncan (1949) and Thompson and Dean (1955) demonstrated that early electroconvulsive shock can destroy the changes produced by learning in rats, whereas learning and memory are not affected if shock is delayed for some period of time after acquisition. Here again, some evidence indicated that these deficits could not be produced by defects in perception, motivation nor attention. Finally, Scoville (1954) Milner and Penfield (1955) and Scoville and Milner (1957) reported cases of bilateral temporal damage who showed almost total loss of recent memory after an interval of five minutes. This loss affected recall as well as recognition, verbal as well as non-verbal material. Past memory, previous knowledge, personality, attention, concentration and I.Q. were relatively unimpaired.

These findings suggest that there is an initial and temporary physiological process, i.e. reverberation,

which maintains a short-lived memory and some time is required for the initial process to take place before it can produce a permanent, perhaps an anatomical, change which forms a basis for long-standing memory.

The main criticism that may be directed against Hebb's theory is that he relied to a great extent on

data derived from experiments using the method of strychnine neuronography; these data are of dubious value (Sholl, 1956, p. 91). Apart from that, he did not attempt to quantify his theory. It is difficult to see in what way such a qualitative theory is predictive in the sense that precise expectations can be verified by experimental facts. ✓

CLAIMS FOR LOCALIZATION OF FUNCTIONS

In this section a brief review of the literature on psychological studies which are concerned mainly with human material will be presented with the aim of illustrating inconsistencies in the various claims concerning localization of functions. Such a review will add further evidence for or against the theories of brain organization and functioning outlined above.

The literature is abundant in various claims for the localization of cognitive and orectic abilities within specific areas of the brain, indicating that the brain does not operate in a unitary fashion with respect to most functions, and supporting the theory of regional equipotentiality. The results, however, are frequently inconsistent and even contradictory as to what functions depend on which areas.

As a matter of convenience it is proposed to review the literature in terms of the respective lobes and cerebral hemispheres and then to discuss more important topics like intelligence, conditioning and learning, and personality. In the next section of the chapter the claims will be critically examined in general terms and the main causes of the disappointing results will be discussed.

Frontal Lobes

By far the greatest number of studies are concerned with the frontal lobes. This is partly due to the traditional view that the frontal lobes are the site of man's intellectual functions and partly because psychosurgery made such cases particularly available.

The literature on the frontal lobes is vast and most of the findings are based on cases of surgery for various pathologies and for the relief from mental disorders. It may be seen from various reviews of the literature on frontal lobe cases (Hebb, 1945; Crown, 1951; Klebanoff *et al.*, 1954; and Chapter 15 of this *HANDBOOK* by R. Willett) that there is a complete lack of agreement as to what cognitive functions are impaired following an injury to the lobes. For practically every study showing impairment of some function, another study can be cited which failed to reveal any such impairment.

A number of workers reported various deficits and some of them attempted to interpret the observed defects in terms of a single concept, and thus to achieve

a theoretical statement of the functions of the frontal association areas. Others, when confronted with the absence of evidence of intellectual deterioration argued that some aspect of intelligence, which is not measured by standard tests, is affected.

Goldstein (1944), Rylander (1939, 1943) and Halstead (1947) reported that frontal lobe cases manifested greatest impairment of intellectual ability and they expressed the notion that the more complex and integrative the function is the more dependent it is on the integrity of the frontal lobes. As regards the nature of the deficit, their opinions differed; Goldstein ascribed all defects to a loss of abstract attitude, Rylander maintained that the basic defect lies in reasoning, and Halstead argued that "biological intelligence is affected." Apart from these, such basic intellectual deficits as loss of the power of synthesis (Brickner, 1936), and creative ability (Hutton and Bassett, 1948) were advanced.

Other workers argued that there are no intellectual changes following frontal lobe injuries and it is possible that the frequently reported cognitive deficits are not directly produced by any pathology but are indirect results of personality changes. Thus, Karl and Elvidge (1955) maintained that the basic loss is lack of motivation, an inability to plan for and to maintain a goal. Freeman and Watts (1942, 1948) contended that frontal lobes are concerned with foresight with respect to self. Robinson (1946) tested and confirmed the hypothesis that there is a loss of capacity for prolonged attention which accounts for most of the deficits. Arnot (1952) argued that the basic function of the frontal lobes is "the persistence of emotional states, chains of thought, motor actions and motor inhibitions."

Several workers attempted to measure personality changes objectively (Crown, 1953; Tow, 1955; Petrie, 1949*a*, 1949*b*, 1952*a*). The main conclusions emerging from these studies were that, following leucotomy, patients showed a temperamental change from introversion towards extraversion and a conative change towards normality on the neuroticism dimension. Crown (1953) adduced some evidence that there is also a decrease in the factor of psychoticism.

Most of the above studies and a number of others,

not quoted here, fail to meet the basic requirements of a valid experiment. In most instances there is a lack of adequate normal controls, the data are rarely treated statistically, and the theoretical statements about the functions of the frontal lobes are not warranted by the findings. Apart from that, as it has been pointed out, most of the positive findings have not been confirmed. For instance, the Columbia-Greystone investigation (Mettler, 1949*a*, 1952) reported that, following ablations of prefrontal and orbital portions of the frontal lobes, there was no evidence of any permanent intellectual impairment. Such mental abilities as learning, memory, associations remained unchanged. The study also failed to show any regular alterations in Goldstein's ability to abstract, and no loss in creative ability, imagination, or high level of intellectual achievements was demonstrated. Finally no change or loss in social or ethical attitude was shown.

Hebb and Penfield (1940), and Hebb (1939, 1941, 1945) found little evidence of intellectual impairment on a series of cases with various frontal extirpations. Hebb (1945) also criticized some of the studies, demonstrating various defects on methodological grounds, and concluded that the various interpretations of the frontal lobe functions are too broad and ill-defined to be meaningful. Apart from that, some of the workers disregarded negative cases in their studies.

What is more important, from the point of view of localization of functions, is that no one has proved that any single form of behaviour is dependent on the frontal lobes or that a damage to this area has any effect on behaviour (Hebb, 1945). Various studies, showing positive results, are of interest in so far as various deficits may follow an injury to the frontal lobes, but inadequate information on the extent of anatomic destruction and pathologic dysfunction produced by injuries, and the frequent lack of adequate controls of other brain-damaged patients make untenable the conclusions that any of the functions reported are *solely* dependent on the frontal association area.

It is relevant to consider here the studies of Rylander (1939, 1943) and Halstead (1940, 1947) since both authors performed systematic mental testing following excision of frontal and non-frontal tumours and included normal controls. Both affirmed that lesions outside the frontal lobes cause no impairment comparable with that found in their frontal lobe cases. The value of their assertions may be questioned. First of all, precise anatomic and pathologic data are lacking; secondly, Rylander deliberately excluded from his control group patients with injury to language areas, and the age differences between the frontal and non-frontal groups in Halstead's study invalidate the

comparison between the two groups. Thirdly, some non-frontal patients showed intellectual impairment which was at least equal to the average for the frontal lobe group.

With respect to the assumption of the predominant importance of the frontal lobes for intellectual functioning, several studies (Battersby, Krieger, Pollack and Bender, 1953; Bauer and Becka, 1954; Battersby, Teuber and Bender, 1953; Teuber *et al.*, 1951; Teuber and Weinstein, 1954; Semmes *et al.*, 1954; Weinstein and Teuber, 1957; Aita *et al.*, 1947; Morrow and Mark, 1955) using various complex tasks, reported results which are incompatible with this notion. They showed that frontal lobe lesions, compared with lesions elsewhere, are not more disruptive of complex intellectual performance.

In conclusion, as Hebb pointed out (1945), it cannot be argued that the frontal association area has no function at all. The research so far available, however, has not conclusively established the dependence of any function on this area.

Left and Right Cerebral Hemisphere

Turning now to the non-frontal regions one finds more consistency in the reported findings, but these results are far from being unequivocal. The most consistent claims are that patients with the left hemisphere lesions (dominant side) are relatively poor at verbal tasks, while those with right sided lesions (non-dominant side) are worse at practical tasks, particularly the manipulation of spatial or spatio-temporal relationships. The possibility of such a differential pattern of functioning associated with the two hemispheres was raised by several studies (Weisenberg and McBride, 1935; McFie and Piercy, 1952*a*; Bauer and Becka, 1954; Patterson and Zangwill, 1944; McFie *et al.*, 1950; Milner, 1954; Morrow and Mark, 1955). Anderson (1951) and Reitan (1955*a*) tested this hypothesis and secured supporting evidence. Heilbrun (1956) confirmed that verbal deficits result from left-sided lesions, but this was true for an unselected population of left-sided cases, since the result indicated that this inferiority was largely a function of poor performance of patients with dysphasic symptoms. The non-language performance deficit associated with right hemisphere lesions was not entirely confirmed by his data. His left and right hemisphere groups produced almost identical scores on spatial tests; right-sided cases did more poorly on the spatial battery compared with their own verbal test performance.

In so far as these workers paid attention to the specific sites of the lesions, their findings indicate that the pattern of test performance is a function of the hemisphere in which the lesion occurs rather than its specific *locus*. McFie and Piercy's analysis of various

deficits in terms of different lobes (McFie and Piercy, 1952a) and a number of other reports on the effects of lesions of the temporal and parietal lobes (to be presented later) appear to be inconsistent with the above findings. It is highly probable that the pattern of test performance associated with the two hemispheres may largely depend on the composition of the groups with respect to the specific sites of lesions. The lack of agreement between the findings of Heilbrun (1956) and those of Anderson (1951) and Reitan (1955a) could be explained if the last two authors included more cases with posterior lesions in their right hemisphere groups than Heilbrun did in his right-sided group.

The localization of speech functions in one hemisphere, usually the dominant one (the left hemisphere in a right-handed person) has been relatively well established. The dominant hemisphere appears to have some sort of executive and organizing role for speech. There is no agreement however, amongst students of aphasia about the nature of speech disorders, their classification, and their precise boundaries within the dominant hemisphere.

Generally speaking, there are three views on aphasia which are equivalent to the three theories of brain organization and functioning already described. On the one hand, Henschen (1920, 1922), Kleist (1934), and Nielsen (1946) classified aphasias functionally and anatomically into a multitude of various specific defects such as alexia, agraphia, amusia, amnesic aphasia, motor and sensory aphasia, and claim that each specific disturbance can be precisely localized within the dominant hemisphere. On the other hand, Goldstein (1948) and Head (1926) opposed the classification of aphasia into specific defects; they also opposed the doctrine that different language functions are differently localized in the left cerebral cortex. Roberts (1951) and Conrad (1954) provided evidence against extreme mechanical views of localization of various disturbances.

A more traditional view, which occupies an intermediate position between these two extremes, uses a loose functional and anatomical classification of aphasias, and maintains that some damaged areas cause one type of disorder more frequently than another, making the difference one of degree only. According to this view, aphasia seen in anterior parts of the dominant hemisphere is predominantly expressive, whereas in posterior parts it is predominantly receptive (Weisenburg and McBride, 1935; Conrad, 1954; Kennedy and Wolf, 1936; Schiller, 1947). There is a considerable amount of evidence that pure types of expressive and receptive aphasia are not frequently found. Weisenburg and McBride (1935), Conrad (1954) and Schiller (1947) demonstrated that the difficulty in word finding (amnesic or nominal

aphasia) can occur anywhere within the "speech areas" irrespective of the site of the lesion. Thus, Weisenburg and McBride pointed out that some expressive defect can always be found in aphasic patients; Schiller, demonstrated that in all cases with true aphasia there is difficulty in word finding. Schuell (1954) showed that no isolated pure disorders of speech were found on a thorough examination of aphasic patients. She postulated (1953; Schuell *et al.*, 1955) that the basic difficulty of these patients is auditory impairment, i.e. difficulty to retain and evoke auditory patterns of language; all aphasic disturbances are believed to be secondary to this basic disorder.

It is clear from the foregoing that damage to the dominant hemisphere results in various speech disorders and deficits on verbal tasks, but it is not clear to what extent aphasic disturbances manifested clinically are responsible for verbal decrements on psychological tests and whether aphasia is purely a verbal disturbance or whether it implies more general intellectual loss.

It is difficult to give a clear-cut answer to these questions since the majority of studies did not exercise a rigorous control of aphasic disturbances. Some studies provided a considerable amount of evidence that verbal test deficits are attributable to aphasic symptoms (Meyer, 1959; Heilbrun, 1956). Others showed that such impairment can be demonstrated in cases with dominant hemisphere damage without clinically manifest aphasic disturbances (McFie and Piercy, 1952a; Rey *et al.*, 1949; Meyer and Jones, 1957). Zangwill (1946) claimed that he could elicit dysphasic symptoms by means of specialized verbal tests in brain-damaged cases who did not show any disturbances of language on ordinary examination.

It appears that clinically manifested aphasic disturbances are responsible for impairment on verbal tests; however, such deficits can be also demonstrated to a lesser degree in cases with dominant hemisphere injury without clinically manifest aphasic disturbances. It is possible that the latter impairment may represent a subclinical condition on the same physiological continuum as clinically manifest aphasia.

With regard to the second part of the problem, there are three views. Goldstein (1948) regards various symptoms of aphasia as manifestation of a single more profound intellectual disorder; according to another, aphasia results in a mere loss of symbols leaving thought processes unimpaired (Kennedy and Wolf, 1936); a third view takes an intermediate position considering aphasia as a disturbance which affects all aspects of intelligence, although not to the same degree, so that performance on verbal tests of intelligence will be severely impaired and a milder deficit will be found on non-verbal tasks (Weisenburg

and McBride, 1935; Hebb, 1942; Fox and German, 1935).

A crucial test for these theories demands the use of non-verbal tasks. The literature bearing on this problem is equivocal. Some workers presented evidence that aphasia is compatible with normal performance on some non-verbal tests (Meyers, 1947; McFie and Piercy, 1952*b*; Brown, 1955; Meyer and Jones, 1957; Meyer, 1959). Others, like Heilbrun (1956), Teuber and Weinstein (1956) supported Goldstein's view to some extent. Most of the empirical support has been provided for the third view (Weisenburg and McBride, 1935; Bauer and Becka, 1954; McFie and Piercy, 1952*a*).

The greatest weakness in these studies lies in the fact that many non-verbal tests involve verbal instructions, hence aphasics may be penalized on them because of difficulty in understanding what is required of them; unless it can be ascertained that the patient has grasped the instructions the results cannot be considered as valid (Kennedy and Wolf, 1936). In addition, Heilbrun (1956) showed that different results may be secured from left-sided cases using non-verbal tests not requiring verbal responses. It is possible that those aphasics who show impairment on non-verbal tasks rely excessively upon verbal cues in solving problems and language disturbances may interfere with implicit verbalization which is used to elicit non-verbal responses.

It is pertinent to say a word about effects of hemispherectomy in man on psychological functioning. The overall evidence (Krynauw, 1950; Mensh *et al.*, 1952; Uecker *et al.*, 1954; Munz and Tolor, 1955) indicates that following excision of either hemisphere neither a pronounced improvement nor a marked decline of intellectual functioning can be found as a rule. Such evidence, however, does not add anything to the problem of localization. Firstly, most of the cases investigated were grossly deteriorated before the surgery and the frequently reported lack of deficits following the operation may be due to the removal of pathological tissue, which presumably exerted a deleterious influence on neighbouring cerebral areas and resulted in various clinical symptoms before the operation. Secondly, practically all cases suffered from congenital defects, hence it is doubtful whether the left hemisphere in right-handed cases was dominant for language functions.

*In summary, the evidence adduced indicates conclusively that the dominant hemisphere governs language functions. As regards the non-dominant hemisphere it appears that non-verbal tasks depend more on it. The nature of the impairments associated with the respective hemispheres has not been investigated adequately, and the formulations, put forward by McFie and Piercy (1952*a*) and by Anderson (1951),

to account for these deficits are essentially speculative. Finally, it is untenable to maintain that a damage, irrespective of its site within a hemisphere, will produce the same test performance deficit commonly associated with that hemisphere.

Temporal Lobes

The present state of our knowledge of the functions of the temporal lobes is still fragmentary. This ignorance is due in part to a preoccupation, until recently, with the frontal lobes and, in part, to a lack of satisfactory clinical material, which mainly consists of cases with brain pathologies, the extent of which it is difficult to delimit. Apart from that, the rare occurrence of bilateral temporal injuries hinders our understanding of temporal lobe functions.

Several studies indicate that, following various abnormalities in the temporal lobes, specific abilities may be impaired. The most consistent finding is that temporal lobe epileptics manifest, as a group, an impairment on verbal tasks compared with non-verbal tasks (Rey *et al.*, 1949; Meyer and Yates, 1955; Quadfasel and Pruyser, 1955). This is apparently inconsistent with the results in cases with hemispheric involvement presented in the previous section. If temporal lobe cases are randomly selected then such a sample should consist of some left- and some right-sided cases; hence one would not expect to find a differential pattern of verbal and non-verbal abilities for the total group, since the verbal decrements in one group would counterbalance the non-verbal decrements in the other group producing no significant discrepancy. None of the investigations into the effects of temporal lobe lesions quoted above, included a statistical analysis of results in terms of lateralization. A possible explanation of the discrepant findings is that epileptic foci tend to occur more frequently in the left than the right temporal lobe. Rey *et al.* (1949) found this in a sample of fifty-nine cases, irrespective of sex, and cited other evidence in support of this view. Hécaen and Piercy (1956) reported a significantly larger proportion of left-sided lesion cases with epileptiform auras and equivalents than similar right-sided cases. Possibly related to these findings are those of Busse *et al.* (1956) who showed focal disturbances of EEG of aged individuals to be almost exclusively temporal in *locus* and left in lateralization. On the evidence of these findings an unselected sample of cases with epileptic temporal lobe EEG abnormalities would consist of a greater proportion of left-sided cases, hence one would expect to find in such a sample a tendency to lower verbal than non-verbal scores. Also, a left-sided sample should show a highly significant verbal deficit, whereas a right-sided sample should produce lower non-verbal than verbal scores. This problem was investigated by

Meyer and Jones (1957) on a sample of temporal lobe epilepsy cases before and after temporal lobectomy for the relief of temporal lobe epilepsy and the findings supported the above hypotheses.

A number of investigators attributed memory functions to the temporal lobes. On the basis of the findings by means of electrical stimulation of the exposed cortex Penfield and Rasmussen (1950) attributed to the temporal lobes a role of perseveration of memory traces. The temporal lobe as a whole is concerned with memory functions and with judgements and assessments of current experience based on memory. The findings of several studies are consistent with Penfield's view (Milner and Penfield, 1955; Scoville and Milner, 1957; Quadfasel and Pruyser, 1955; Kolodny, 1928; Fox and German, 1935; Keschnier *et al.*, 1936; Scoville, 1954; Walker, 1957). These reported various deficits in memory processes following temporal lobe injuries. The situation, however, is far from being simple. The evidence from animal studies indicates that bilateral removal of the temporal lobes in monkeys does not result in a general loss of memory (Milner, 1954). The investigations previously quoted (Milner and Penfield, 1955; Scoville and Milner, 1957) reported that bilateral temporal damage in man, when the damage includes the anterior hippocampus and hippocampal gyrus, results in a persistent and generalized impairment of ability to record current experience, whereas the retention for past events remains unaffected. It appears then that past memory is not "stored" in the temporal lobes, but that these structures are important for the "recording of current experience." Quadfasel and Pruyser (1955) presented results which indicate that cases with psychomotor epilepsy and an EEG spike focus in the anterior part of the temporal lobes produced a memory deficit on test items involving verbal material and the auditory modality, but no such deficit was demonstrated on non-verbal items requiring the visual modality. These findings do not entirely support Penfield's view and the overall evidence indicates that only general registration of recent events is impaired following bilateral damage to the temporal lobes. Apart from that, unilateral damage appears to affect mainly registration of auditory material.

These studies, however, suffer from several defects which undermine the value of the conclusions drawn with respect to the nature of the deficits and their association with the temporal lobes. Firstly most of the reports are of a clinical nature with little or no attention paid to statistical evaluation of results. Secondly, they lack adequate normal and other brain-damaged controls. Thirdly, the extent of anatomical destruction and physiological dysfunction is not precisely determined. For instance, an attempt to

localize the impairment of ability to record current experience, following bilateral medial resection, in specific regions of the temporal lobe (Scoville and Milner, 1957) is somewhat inferential, since the operations were done "blind." Fourthly, it is impossible to generalize from the limited findings to learning ability in all modalities for various types of materials. Finally, no attempt has been made to evaluate results in terms of the laterality of abnormalities and various relevant factors like intelligence and language disturbances have been left uncontrolled.

Milner (1954) pointed out, and adduced some evidence, that any evaluation of temporal lobe functions in man requires a breakdown into left and right temporal lobe lesions. In a preliminary study, Meyer and Yates (1955) reported results which are consistent in a way with the conclusions reached by Kolodny (1928), Fox and German (1935) and Keschnier *et al.* (1936) in that temporal lobectomy cases demonstrated a pronounced impairment of learning verbal material presented auditorily. This impairment appeared to be associated with the operation on the dominant side only. Meyer (1959) attempted to investigate the nature of this deficit on a larger sample of dominant and non-dominant temporal lobectomy cases. Learning ability was assessed in the auditory, visual and tactile modalities for various types of material and methods of testing. Also, an attempt was made to determine to what extent nominal dysphasia contributed to the impairment of auditory learning manifested by the dominant group, and the possible influence of intelligence was taken into account. The findings indicated that dominant cases consistently showed a highly significant and persistent deficit on the auditory learning tests only. Since this impairment was in evidence on recall as well as on recognition mode of testing, it could not be accounted for solely in terms of nominal dysphasia. The difficulty was shown to be of acquisition and not merely of execution; the failure to learn following the operation was not correlated with intelligence level. The non-dominant group did not show any changes on any learning tests.

Since the aim of this study was to investigate the effects of temporal lobectomy on cognitive functioning and to define more closely the nature of any deficits detected, the results have no direct bearing on the problem of localization. It cannot be argued that auditory learning depends exclusively on the integrity of the dominant temporal lobe; but the findings indicate that this function does not depend on the integrity of the non-dominant temporal lobe and that visual and tactile learning abilities are independent of the integrity of either temporal lobe.

A number of results, probably related to those just discussed, indicated an impairment on various tests

involving auditory modality, i.e. auditory pattern discrimination tests (Bauer and Becka, 1954), auditory flicker fusion test, auditory pattern association test, multisensory timing test (Halstead, 1955) and conditioning of EEG alpha response to a sound stimulus (Morrell, 1956). Halstead (1955) claimed that his new auditory tests detect unilateral temporal lesions at the 0.01 level. Some findings, however, are not consistent with those above, and it cannot be maintained that the auditory modality *per se*, irrespective of the nature of tasks, would be impaired as a result of injury to the temporal lobes. Thus Symmes (1955) using the multisensory timing test, concluded that the auditory problem does not discriminate between a group with the absence of tissue or the presence of focal epileptogenic lesion in the temporal lobe on the one hand and a group with the intact temporal cortex on the other. Chapman *et al.* (1955) reported that the degree of impairment on the auditory flicker fusion test appeared to be constant for several sites of cortical lesions studied. Morrell's cases with temporal epileptogenic lesions, manifesting an impairment in the ability to form a conditioned alpha response to a sound stimulus, did not show an impairment of the voluntary motor reaction to a tonal stimulus (Morrell, 1956).

The investigators discussed above failed to analyse the results in terms of laterality. Since the neurophysiological evidence "localizes" the auditory recognition within the dominant hemisphere (Nielsen, 1946) and since in the temporal lobe aphasia the auditory components of speech are impaired, with difficulty both in understanding and in retaining spoken language (Fox and German, 1935; Kennedy and Wolf, 1936; Nielsen, 1946; Schiller, 1947; Teitlebaum, 1942) one would expect to find impairment on various tests involving the auditory modality in cases with damage to the dominant temporal lobe only. Meyer's findings (1959) are consistent with this in demonstrating that only dominant temporal lobectomy cases manifested impairment on auditory learning tests, and in presenting some evidence that this deficit may be related mainly to the defective auditory modality resulting in a difficulty of registration and retention of auditorily presented material.

Apart from the above studies, various findings, related to the temporal lobes, have been reported. These are equivocal and inconsistent. Milner (1954) quoted studies of monkeys to show that bilateral removal of the temporal lobe severely impairs visual learning and retention. This deficit is particularly severe on tests of pattern discrimination. The critical area in this effect appears to be a small region on the ventral surface of the temporal lobe, damage to which is almost as detrimental to visual learning as is complete lobectomy. She also presented data on human

subjects which, according to her, are comparable with the animal studies and in agreement with them. Her temporal lobe cases, as a group, were inferior to the controls, both before and following unilateral temporal lobectomy, on visual tests involving complex pictorial material. She concluded that the deficit appears when "attention has to be given to many aspects of a complex picture, or when different pictures have to be arranged in a meaningful order on the basis of slight differences in detail." Reitan (1955), however, using the same test, detected similar defects only in cases with right temporal lesions. Bauer and Becka's (1954) results are inconsistent with Milner's and Reitan's findings since her visual discriminative tasks did not differentiate temporal lobe cases from cases with lesions elsewhere. Battersby *et al.* (1955, 1953) evaluated results on visual and tactile discriminative learning in the light of animal studies and in the light of Milner's claim attributing to the temporal lobes an integrative focus for the elaboration of visual impulses. Their findings failed to support such a view.

Consistent with the deficits found in cases with right hemisphere lesions, there are several studies which reported that right temporal lobe lesion cases manifest impairment on tests of a visuo-spatial nature. Hebb's case showed a defect of form perception, visual and tactual (Hebb, 1939); McFie *et al.* (1950) reported in their case of right temporal glioma a severe loss of "visuo-constructive ability." Milner's other finding was that the right temporal lobe group was inferior to the left temporal group and to frontal and parietal cases as a control group on tests of spatial patterning, both visual and tactual, the deficit being present before the operation but intensified afterwards (Milner, 1954). The most pronounced deficit was manifested by cases in whom the extirpation extended far back along the inferior surface of the temporal lobe. Probably related to these findings are those of Teuber and Weinstein (1954) who reported the right temporal group to show "negative transfer" on the Seguin-Goddard form board test rotated 180°. Meyer (1959), however, found little evidence for the above findings in his group of right temporal damage.

A further inconsistency, probably having some bearing on the visuo-spatial functioning, was added by two studies. Elithorn's findings suggested that a multiple-choice maze test is particularly sensitive to cerebral damage to the temporal lobes. His frontal group, submitted to the full type of leucotomy, performed significantly worse on this test also. Semmes *et al.* (1955) and Weinstein *et al.* (1956), on the other hand, demonstrated that the integrity of the temporal lobes is not important for spatial orientation (route finding) and that this ability is associated to some extent with the parietal lobes and most strongly associated with severe somaesthetic defect.

Finally, Semmes *et al.* (1954) reported her brain-damaged temporal group to be significantly inferior to other brain-damaged groups without temporal lobe lesions on complex tactual tasks. This, however, was not confirmed by Bauer and Becka (1954) and Battersby *et al.* (1955).

It is difficult to resolve the above inconsistencies since in most instances there is a lack of the relevant information to enable one to evaluate and to compare critically the reported findings. On the basis of the foregoing it can be concluded that damage to the dominant temporal lobe results in an impairment on verbal tests. This impairment is most likely to be partly due to a defective perception of auditory components of speech and partly due to nominal dysphasic disturbances. Apart from that, some evidence suggests that a deficit on various tests involving the auditory modality may be demonstrated, particularly on auditory learning tests. This deficit may be mainly related to an impairment of the auditory modality resulting in a difficulty in the registration and retention of auditory stimuli.

Non-dominant temporal lobe injury is most likely to result in a deficit on tasks of a visuo-spatial nature. Some evidence suggests that the more posteriorly the injury is placed the more severe is the deficit. The nature of this deficit has not been clarified.

Limited bilateral destruction of the temporal lobes has been demonstrated to result in a generalized and severe loss of ability to register recent events.

As regards the problem of localization the data do not provide a conclusive proof for the dependence on the temporal lobes exclusively of any of the functions reported.

Parietal and Occipital Lobes

These areas of the brain are not discussed separately in any detail, since it is difficult to obtain cases with damage to one without the other being affected. This is due to the fact that these areas are in close vicinity and merge into each other without a clear demarcation line.

A great many studies have directed attention to the effects which follow posterior lesions; the majority of these, however, contain clinical case reports and very few employ objective psychological tests and fulfil the basic requirements of a valid investigation. Semmes *et al.* (1955) quote some thirty such studies according to which disorientation in space is a prominent sequel of damage to the parietal lobes. A great number of such disturbances have been reported (Critchley, 1953). Some of these can be accounted for in terms of primary sensory and motor impairment or in terms of dementia; others are regarded as agnosias or apraxias since they are demonstrable in the absence of sufficient evidence for primary dysfunc-

tion or a general intellectual loss. The following defects of function have been reported: anosognosia (denial of illness), neglect of half of the body or of external space, difficulties in estimation of direction and distance of objects, confusion of right and left, apraxia for dressing, anomalies in constructional tasks, inability to follow habitual routes, and defects in place recognition. However, the evidence is equivocal as regards localization since many of the above alterations of functions have been reported to occur after damage to the occipital, temporal, and even frontal lobes (Weinstein and Kahn, 1950; Battersby *et al.*, 1956; Teuber and Mishkin, 1954; Teuber and Bender, 1949).

Several investigators have attempted to clarify the nature of space orientation, and to relate various disturbances to the left or to the right parietal lobe. Most of the conclusions are not based on objective facts and are essentially tentative. Weinstein *et al.* (1956) pointed out that discussions of the nature of the deficits centred around three hypotheses. The first regards spatial disorientation as a form of visual agnosia. The second suggests that the defect is confined to vision involving the primary aspect of sensation rather than the "higher organization" of sense data. The third maintains that spatial disorientation reflects general intellectual loss.

Some attempts have been made to test these theories more objectively by controlling relevant factors. Battersby *et al.* (1956) concluded that neither visual nor concomitant somatosensory defects could account for unilateral spatial inattention; those cases which showed the spatial deficit had, in addition to primary sensory defects, mental alterations. Ettlinger *et al.* (1957) concluded that disorders of visual space perception demonstrated by cases with right posterior lesions cannot be entirely accounted for in terms of impairment of differential visual sensitivity, unilateral visual extinction, central vestibular derangement, or in terms of a combination of these factors. Nor can such disorders be viewed as secondary to general intellectual impairment. The authors attempted to explain visuo-spatial disorders in terms of restriction of "the field of visual attention" associated with some degree of conceptual spatial loss. The best attempts in this field of research have been made by Semmes *et al.* (1955) and Weinstein *et al.* (1956). These investigators demonstrated that spatial disorientation (route finding) cannot be entirely explained as a loss of general intelligence, nor can it be regarded as visual or tactual agnosia. Also, they demonstrated that this deficit cannot be ascribed to the receptive difficulty in visual or tactile modality. Their data indicated that spatial disorientation is mainly related to severe somaesthetic defects, hence they play down the importance of the parietal lobes for mediating

spatial functions. On the whole, these findings are consistent in so far as they do not support any of the hypotheses put forward to explain the nature of space disorientation.

Various clinical claims ascribe some disturbances of space orientation to both parietal lobes, some exclusively to the right or the left lobe. These claims have been summarized by Hécaen, Penfield, Bertrand and Malmo (1956). On the whole, the evidence is controversial and the differences between the lobes are not understood. There are some suggestions, supported to some extent by psychological test results, that right parietal lesions result in a failure on visuo-constructional tasks due to the lack of visual discriminative judgement (spatial agnosia) whereas damage to the left parietal lobe produces impairment on such tasks due to constructive apraxia (McFie and Piercy, 1952a; McFie *et al.*, 1950; Zangwill, 1954).

Functions other than space orientation have been associated with the parietal lobes but the findings are rarely consistent. Since lesions to these areas are supposed to result in tactile deficits and tactile agnosia (Nielsen, 1946), one would expect cases with parietal-lobe damage to manifest greatest impairment on tasks involving the tactual modality. The following are consistent with this hypothesis, Jaffe's findings on tactual adaptation (Jaffe, 1955); Semmes *et al.* (1954) on transfer effect with regard to performance on complex tactual tasks, Bender *et al.*, (1950) on barognosis, and Weinstein on negative time error in weight judgement (1955c). Weinstein, however, failed to demonstrate that parietal lobe cases showed greatest deficit on tests of barognosis (Weinstein, 1954), tactile size judgement (Weinstein, 1955a) and time error in tactile size judgement (Weinstein, 1955b). In addition performance on various complex tactual tasks did not discriminate parietal lobe cases from cases with lesions elsewhere (Bauer and Becka, 1954; Semmes *et al.*, 1954; Battersby, Krieger and Bender, 1953; Ghent *et al.*, 1955a; Battersby *et al.*, 1955; Ghent *et al.*, 1955b).

These results are further complicated in that Bender *et al.* (1950) and Weinstein (1955c) reported that deficits of weight judgement, related to parietal lobe damage, were not necessarily associated with concomitant somatosensory defects. Similarly, the defective performance of brain-damaged patients in general on various complex tactual tasks was demonstrated by some investigators to be independent of somatosensory defects in the hand involved (Battersby *et al.*, 1955; Ghent *et al.*, 1955b; Battersby, Krieger and Bender, 1953; Weinstein, 1954). On the other hand some evidence indicated that such impairments are related to somaesthetic defects (Ghent *et al.*, 1955a; Weinstein, 1955a) and that the direction of the error may be determined by the presence of

somatosensory status (Weinstein, 1954). The results reported on size and weight judgements (Bender *et al.*, 1950; Weinstein, 1954, 1955a, 1955b, 1955c) are further complicated by the bilateral and unilateral testing of hands.

Further inconsistency with regard to the parietal lobes may be found where arithmetic ability is concerned. Some investigators found that cases with right parietal lesions were inferior on arithmetic tasks (Weisenburg and McBride, 1935), others reported such impairment particularly in cases with left lobe damage (McFie and Piercy, 1952a; Strauss and Lehtinen, 1950).

The results are not clear as to what functions are dependent on the integrity of the occipital lobes. Changes on tasks in the field of vision have been shown to occur (Bender and Teuber, 1949; Teuber and Bender, 1949), which are consistent with the view that lesions to the visual cortex produce primary visual dysfunctions and disturbances of higher functions, i.e. visual agnosia (Nielsen, 1946). These have already been enumerated. Teuber and Bender (1949) pointed out that their cases did not contribute to the solution of the problem of localization, since many of them had other parts of the brain injured as well as the occipital lobe. Apart from this, some of the tests employed were measures of spatial orientation rather than of pattern vision proper, and it has already been pointed out that deficits on the former type of test are usually associated with the parietal lobes. Furthermore, deficits on various complex visual tasks frequently failed to discriminate cases with occipital lobe damage from cases with lesions elsewhere (Battersby *et al.*, 1955; Bauer and Becka, 1954; Battersby, Krieger and Bender, 1953).

No direct light was thrown on the nature of impairment of visual tasks following damage to the occipital lobes. An investigation into the relation of such impairment to changes in primary sensory defects would present a considerable difficulty, since damage to the geniculocalcarine system not only produces circumscribed scotoma, but also impairs visual functions over the entire field of vision (Bender *et al.*, 1951). Indirect evidence on brain-damage cases in general indicates that deficit on various visual tasks is relatively unaffected by the presence of primary sensory defects (Battersby *et al.*, 1955; Battersby, Krieger and Bender, 1955; Weinstein *et al.*, 1955). Surprisingly, some measures of tactual defects have been reported to be associated with defective performance on some visual tests (Weinstein *et al.*, 1955). Finally, some indirect evidence shows that deficits on visual tasks cannot be described as visual agnosia since the same lesions that impaired performance on visual tasks interfered with performance on tactile tasks (Battersby *et al.*, 1955; Battersby, Krieger and Bender, 1953).

Some of the studies described above, particularly

those by Semmes *et al.*, (1955) and Weinstein *et al.*, (1956), indicate that different results may be obtained with regard to localization of functions by means of analysis according to the *locus* of the lesion and by analysis according to concomitant defects. Thus the value of the available data on functions of the occipital and parietal lobes is further undermined by the fact that most of the investigators failed to examine systematically the relationship between performance on various tests to the presence or absence of other concomitant defects produced by the brain injury. Furthermore, those who did exercise such control did not attempt to localize concomitant defects.

When all the data have been taken into account, the only conclusion that can be drawn concerning the parietal and occipital lobes is that damage to the former is particularly apt to produce impairment on tasks involving spatial functions, and damage to the latter is to result in deficits on tasks making use of visual functions.

Intelligence

Despite sustained interest in the effects of cerebral lesions on general intelligence, there is no agreement on the localization of those injuries which might produce maximal deficits on tests designed to measure this function.

The results do not support Lashley's view on brain functioning, nor the claims which attribute to the frontal lobes the predominant importance for intellectual functioning. The uncertainty is enhanced by a number of reports which failed to detect deficits on tests of I.Q. following a destruction of large parts of the human brain (Hebb, 1949; Meyer, 1959; Hebb, 1945; Mettler, 1949a; Uecker *et al.*, 1954; Munz and Tolor, 1955).

Most of the information concerning changes in and localization of intelligence following brain injury is of limited and doubtful value. Firstly, it is based on samples of cases which are not representative of the brain-damaged population; these samples are mainly frontal lobe cases. Secondly, those investigators who used controls failed to equate them adequately with their brain-damage cases on all relevant variables. Thirdly, those who compared pre- with post-operative performance based their estimates of changes in intelligence on abnormal scores of both assessments. Since the premorbid scores are unknown, such estimates are rendered doubtful by the extent to which brain injury or mental disorder might have affected the patient's performance before the operation or continued to affect it after. It is particularly difficult to assess changes after psychosurgery since post-operative alterations in mental disorders complicate the issue, e.g. reported improvements may, frequently,

compensate for deficits which would have been evident as a result of surgically induced damage.

The best information concerning the problem of localization of intelligence is provided by Weinstein and Teuber (1957). The authors compared scores on a standardized test of intelligence (Army General Classification Test) obtained from patients with penetrating brain injuries, approximately ten years after they had been wounded, with corresponding scores achieved before the injury. Controls, who have sustained peripheral nerve injuries, were also included in this study and tested in the same way as the experimental group. The pre-injury mean scores of both groups were practically identical. The brain-injured sample was subdivided into groups according to the estimated location of their lesions and the results were submitted to analyses of variance. The findings indicated that the group with left parietal or left temporal lesions exhibited a significant decrease, but that this decrease was mainly a function of aphasic disturbances. The most striking decrease in intelligence was produced by the group with left parieto-temporal injury compared with all other groups and a loss was still demonstrable when the aphasics were excluded from this group.

The main criticism which can be directed against this excellent study is that the localization of lesions was tentative, and intelligence was "narrowly" assessed. The previously quoted investigations (Meyer, 1959; Meyer and Yates, 1955) compel caution in drawing conclusions with regard to intelligence level following brain injury if assessment is restricted to one type of I.Q. test; the authors demonstrated that general intelligence may remain relatively unimpaired if assessed on tests not involving the patient's specific disabilities.

In view of the evidence adduced which associates damage to certain areas of the brain with deficits of various specific abilities, one may wonder why brain-damaged cases are frequently unimpaired on such I.Q. tests as the Wechsler, which is composed of subtests involving a wide variety of specific abilities. The main reason is that the test was designed for the measurement of general intelligence and, in accordance with this aim, the subtests were selected as valid measures of this ability and, as such, intercorrelate highly. Various attempts to discriminate organics from non-organics by means of Wechsler subtests have been unsuccessful (Yates, 1954). Specialized tests, designed to detect subtle cognitive changes, have been more successful than the standardized, more general tests. In view of this, it is dangerous to conclude that a patient is unimpaired following brain injury if the I.Q. level remains unchanged. This point is well illustrated by Hebb (1939) and Meyer (1959, 1955).

As with the other specific functions which have been discussed, no one has conclusively established the dependence of general intelligence on any one part of the brain.

Conditioning, Learning and Retention

The proposition that modifications in behaviour depend upon modifications within the central nervous system (C.N.S.) is acceptable to most contemporary psychologists. A great many of the studies which have been concerned with the problem of neurological changes following modifications in behaviour and attempts have been made to establish the *locus* in the C.N.S. essential for conditioning and learning. We shall restrict our discussion to the problem of localization.

Most attempts at localization have been performed on animals. Various reviews of the literature (Osgood, 1953; Harlow, 1953; Teuber, 1955; Stellar, 1957; Morgan, 1951; Zeigler, 1957) indicate that the findings, despite relatively well-controlled experiments, have their limitations and do not permit firm conclusions to be drawn with regard to localization and the principles of cortical functioning.

Since very little is known about human material, it may be useful to present briefly the conclusions obtained from animal studies. According to Osgood (1953, pp. 474-494), it appears that cortical tissue is not necessary for conditioning, as the subcortical centres are capable of eliciting conditioned reactions. The evidence suggests that conditioned reactions are organized simultaneously in the cortex and the subcortical centres. The cortex, however, does seem to have facilitating and inhibitory effects upon subcortically organized mechanisms. It also appears that, on the afferent side, the *locus* of the modifications necessary for association to occur is subjacent to the peripheral receptive and projective systems. As regards the efferent side of association, it is not clear whether occurrence of motor response in conjunction with conditioned stimulus is sufficient condition for learning to take place, nor whether motor response is a necessary condition for formation of associations. Culler's (1938) experiment is of great importance since he provided some evidence for localization of a formed association. He traced electrically a small spot in the cortex of a dog which evoked a motor response, previously established by means of conditioning to an auditory stimulus. This spot did not have such effect before conditioning nor after extinction. Its *locus* was not in the sensory nor motor projection areas, but was formed in a bordering "association" area.

As regards simple learning tasks, the evidence suggests that other regions (probably subcortical) may act vicariously for the destroyed parts of the

cortex, and the more difficult tasks appear to depend on the cortical areas since they cannot be relearned after ablation of the areas responsible for the original learning. Learning functions are progressively more dependent on the cortex, and are accompanied by increasingly strict localization (equipotentiality within limited areas) as we move up the phylogenetic scale with increased encephalization.

A considerable amount of work has been done on monkeys in an attempt to discover neural correlates of modifications in behaviour. Morell *et al.* (1956) investigated the effects of epileptogenic lesions on the establishment of conditioned EEG rhythms to visual, tactile and auditory stimuli. The results showed a marked impairment only in the conditioned stimulus that involved the sensory area in which the lesion was produced. A lesion in the amygdaloid region produced a more general impairment affecting the establishing of conditioned reflexes to both auditory and visual stimuli. A focus in the frontal cortex had no effect at all. It is interesting and puzzling that the subsequent excision of the discharging lesions resulted in normal capacity for the formation of conditioned responses.

Chow and Hutt (1953) concluded that the most noteworthy results following ablation of the association cortex in monkeys are: impairment of delayed reaction after removal of frontal cortex; deficits of visual discrimination after damage to the rostral part of the middle temporal gyrus; deficit in taste discrimination following removal of the fronto-temporal cortex and insula. Apart from that, some evidence indicated that less pronounced deficits of somaesthetic discrimination and conditioned reactions can be found as a result of damage to the frontal, temporal and parietal association cortex. The authors pointed out that, owing to various flaws in most studies, the findings are of doubtful value with respect to localization. The greatest difficulty lies in defining and distinguishing the association cortex from the projection cortex; for this reason, studies using ablation techniques need to exercise more rigorous anatomical control. Also, the investigations are wanting in statistical analysis of behavioural data and in careful analysis of the nature of impairments.

Recent interest in the role of the reticular activating system and the rhinencephalon stimulated attention to the investigations of subcortical structures. Very few studies have been reported and the findings are not consistent. Thus some workers (Chow, 1954; Peters *et al.*, 1956) failed to demonstrate impairment of various discriminations, delayed reactions, and conditioned reactions following lesions to thalamic association nuclei (pulvinar and medialis dorsalis). Others (Schreiner *et al.*, 1953; Pechtel *et al.*, 1955) showed that larger lesions in the medialis dorsalis of

cats produced impairment in various simple learning tasks.

There is some evidence that different aspects of learning may be differentially localized. Thus subcortical stimulation of the septal region markedly enhanced the performance of cats and rats on learning tasks, as if the shock constituted a reward (Olds and Milner, 1954; Sidman *et al.*, 1955). Not all the areas explored were rewarding. Negative reinforcement was demonstrated in cats where the fear evoked by stimulation of certain subcortical regions could be used to motivate avoidance behaviour (Delgado *et al.*, 1954; Delgado, 1955). For a detailed and critical review of the studies of the psychophysiology of learning and motivation using electrical stimulation of the brain the reader may be referred to Zeigler (1957).

Human material provides more complex data. This is due to the limited possibility of experimenting on human beings, and the lack of control over the *locus* and extent of lesions; at the same time it is possible to test and to determine more precisely than in animals the nature of a defect in function in a species which can communicate verbally.

A number of studies have been concerned with eliciting quantitative and qualitative differences in motor and autonomic conditioned responses in organic and non-organic patients. Since their ultimate aim was to use any discovered differences for differential diagnostic purposes, they provide little information on localization and neural correlates related to these functions. The results of these studies have been briefly summarized elsewhere (Reese *et al.*, 1953) and the authors concluded that patients with various intracranial pathologies show marked deficiencies in learning motor, autonomic, and discriminative conditioned responses.

In a study previously quoted (Morrell, 1956) Morrell investigated cortical functions involving the auditory system in patients with sharply localized temporal lobe foci and with clinical symptoms suggesting a temporal lobe origin. The results indicated that while there was a marked impairment in the ability to form a conditioned alpha response to a sound stimulus, the motor reaction-time in these patients was unimpaired to both the tone and tactile stimulus.

It has already been pointed out that studies concerning learning ability are wanting in a systematic assessment of this ability, and that the findings are equivocal. Some investigations have indicated that the learning of various tasks is a function of the brain as a whole (McFie and Piercy, 1952a; Battersby *et al.*, 1955; Zangwill, 1946), is related to the size of lesion (McFie and Piercy, 1952a) and unrelated to sensory defects (Battersby *et al.*, 1955). The present author (Meyer, 1956, 1959), on the other hand, has

demonstrated impairment of auditory learning following temporal lobectomy of the dominant side, and this impairment was unrelated to the size of the injury. No such deficit was found in the non-dominant cases. Also, no visual nor tactile learning deficits could be elicited after the operation, on either side. Ghent's *et al.* findings (1955b) complicate the issue further, demonstrating that, regardless of the *locus* of the lesion and regardless of whether there were sensory defects in the hand tested, only the hand contralateral to the injury was inferior in learning a tactual discrimination.

Clinical experience with brain-damaged subjects indicates that defective retention, particularly for recent events, is a common symptom. Very few objective studies concerning the status of memory have been reported. McFie and Piercy (1952a) concluded that their results tended to confirm the view that impairment of retention, like impairment of learning, is related to the size rather than to the *locus* of cerebral lesions. Some findings indicated that the inability to estimate the duration of time after preceeding practice did not seem to be related to lesions in any particular cerebral area (Guthrie *et al.*, 1955b; Weider *et al.*, 1955). Williams and Pennybacker (1954), on the other hand, reported that memory impairment was most common when the area surrounding the floor and walls of the third ventricle was disturbed. The studies previously discussed which were concerned with the functions of the temporal lobes, ascribed the greatest impairment of memory for recent events to the bilateral damage to this region of the brain.

The criticisms, previously directed against studies on learning, hold for investigations of memory. As regards the latter, the greatest weakness lies in the lack of control for different stages of the memory process. Several authors have noted that the notion of memory contains within it several stages or phases which can in fact be considered common to the memory process (Hull, 1917; Ingham, 1949; 1952; McGeoch and Irion, 1953, p. 6).

In its broadest sense the process of memory is commonly divided into three sections: the phase of acquisition of material (the learning phase), the phase of retention, and the phase of reproduction or recognition (Ingham, 1949; 1952). This division is, of course, artificial, since all learning involves retention. It is customary to speak about learning when a short time elapses between acquisition and reproduction, and about retention when the interval is longer. Before retention proper can be tested adequately, it is important that learning to a criterion be established in order that differences in rate of learning may be controlled. Hull (1917) showed that patients of various clinical groups were

significantly inferior to normal controls in the acquisition of material, but when the acquisition was controlled, and material learned to a criterion by controls and patients, the patients were not inferior to controls in reproducing material after a one-week interval. Thus, these results suggest that the memory impairment found in various clinical groups is caused by failure in the acquisition phase rather than that it is due to failure in retention. This finding throws doubt on the validity of so-called memory tests where the acquisition phase is not controlled. In addition, Eysenck and Halstead (1945) demonstrated that the practice of testing memory by the usual clinical tests is unsound, and that these tests measure intelligence rather than memory.

It is clear from the foregoing discussion that no conclusions can be drawn with regard to localization and neural principles underlying conditioning, learning and retention.

Personality

Most information concerning localization of orectic factors in the brain is based on animal studies. Various subcortical areas have been associated with the control of various emotional and motive states (Stellar, 1954). The reticular activating system has been implicated not only in the control of consciousness (Delafresnaye, 1954), but also in the control of emotional behaviour (Lindsley, 1951). Some have emphasized the importance of the rhinencephalic system in emotion, particularly the limbic system and hippocampus (McLean, 1954).

It is sufficient to refer the reader to two brief reviews of the recent literature on this topic (Teuber, 1955; Sprague *et al.*, 1955) to show that many of the findings are equivocal and that they do not allow clear orientation. The main weakness of these attempts at localization is, first, that the nature of the orectic traits is undefined; and second, that the assessment by the experimenter may not be valid or reliable.

Investigations of personality changes in human subjects following brain lesions and surgical interventions have been based mainly on projective tests. Such studies are of little value in solving the problem of localization and brain functioning in relation to personality factors. Firstly, most experimenters assumed implicitly that the brain functions in a "unitary" fashion and accordingly their samples of brain-damaged cases were selected without considera-

tion of the nature of lesions or their localization. Secondly, the main aim of these studies was to derive "signs" which would differentiate organics from non-organics. Thirdly, no effort was made to establish the reliability of these signs and there is little evidence that such tests as the Rorschach can be regarded as reliable and valid measures of personality factors (Payne, 1955). *See also* Chapter 15 of this HANDBOOK.

The only work, known to the author, that attempted objectively to measure personality changes following various types of frontal lobe operations, suggested that various parts of the brain may be contributing differentially to the different personality factors (Petrie, 1952*b*, 1954; Le Beau and Petrie, 1953*a*, 1953*b*, 1953*c*; Petrie and Le Beau, 1956).

The personality changes were measured by objective psychological tests which are related to Eysenck's dimensions of personality (Eysenck, 1947, 1952).

The authors claimed that all convexity operations, i.e. complete standard leucotomy, partial rostral leucotomy and circumscribed selective surgery in the region of the convexity (Brodman's area 9 and 10) were followed by a decrease in introversion and neuroticism. The more extensive the operation the more pronounced the changes which ensue. The greatest decrements along these continua were shown after the standard leucotomy and the least pronounced changes resulted after the most circumscribed operation involving Brodman's areas 9 and 10. Cingulectomy, on the other hand, presented a different picture; there was no evidence of decreased introversion, but psychoticism decreased. Circumscribed excisions in the orbital region resulted in changes which were intermediate between those after the selective surgery of areas 9 and 10 and those after cingulectomy. All the above operations decreased neuroticism, but this change was least marked after cingulectomy.

A limited finding suggested that unilateral left-sided operations may produce a pattern of changes closer to the effects of bilateral operations than was produced by unilateral right-sided operations.

These findings are of great interest and would be more convincing if normal controls had been used and more detailed statistical analysis of the data carried out. As they stand, they suggest that different frontal operations result in differential changes of personality variables, but the dependence of these variables on any area of the brain has not been conclusively established.

CRITIQUE

The main reasons for the inconsistencies of psychological findings and for the failure to develop an acceptable theory of brain functioning have been

discussed at some length by Hebb, (1945) and in *The Organization of Behavior*, pp. 275-289 (1949) and by the present author (Meyer, 1957), and brief references

to some of these reasons have been made in the previous sections of this chapter. It may, however, be helpful to recapitulate the main points and to present additional points which have not been mentioned previously.

Localization of Lesions. Anatomical and Physiological Sources of Error

The main cause of the disappointing results of psychological studies are difficulties and errors in localizing lesions. Before the presence or absence of a psychological function can be ascribed to a particular region of the brain, the extent of anatomical destruction and physiological dysfunction produced by the lesion must be accurately delimited.

PATHOLOGICAL LESIONS

An anatomical injury to the brain, whether atrophic, neoplastic or traumatic, does not affect only the region of the brain tissue that it occupies, but it can also induce alterations in distant parts of the brain. This may occur either from contiguous cerebral oedema, from transfer of intracranial pressure, or from the disruption of connexions between anatomical centres (Dandy, 1933). Apart from that, pathologically affected tissue may interfere physiologically with normal cerebral functioning in neighbouring tissue. This may be due to chemical changes in pathological cells which result in an alteration of the pattern of cell action and which, in turn, may affect adversely neighbouring cells, or even the rest of the brain, through abnormal cerebral activity (synchronous activity) (Hebb, 1945).

Degenerative processes and vaso-spastic episodes are of little value in the problem of localizing functions since the former are widespread (Dandy, 1933) and the latter are typically transient.

Errors in localization can be reduced by data obtained from pneumo-encephalographic and electro-encephalographic studies. These data, however, are far from precise. The amount of error may be reduced by data derived from histological studies after necropsy. Such studies are of infrequent occurrence, and since "dead brains" are the subject of the examination, the deleterious physiological effects of the pathological tissue cannot be determined.

SURGICAL LESIONS

The errors in localizing these are fewer since the amount of outright destruction is known, but one can never be certain that the removal constitutes the only lesion. In the case of tumours the brain is frequently so much distorted that it is difficult to determine anatomically the extent of excision, and in addition distant effects may be present. The removal of even small well circumscribed lesions or epileptogenic foci,

where there are no underlying macroscopic abnormalities, often results in post-operative trauma (scars, oedema); and also the above mentioned physiological changes may occur. In all probability, neighbouring tissue will, subsequently, be adversely affected, and so add somewhat to the total volume of tissue removed.

It can, therefore, be seen that, in order to draw precise conclusions with regard to the problem of localization of functions, it is essential to know whether disturbances are due to (a) anatomical destruction (or surgical removal) restricted to the region of the brain involved, (b) permanent change in the remaining part of the brain, (c) permanent physiological dysfunctions induced by pathology on neighbouring tissue, or (d) transient physiological disturbances. Such information is very rarely available.

Disregard of the possible Differential Effects Following Various Types of Lesions

Another source of inconsistent findings is the tendency to lump together cases with various types of lesions, or to use a sample of cases with one kind of brain pathology and to generalize from the findings obtained to brain damage in general. The evidence indicates that not only can different types of lesions in the same *locus* produce quite different results, but also that apparently similar lesions, with respect to the type, *locus* and size, may have dissimilar effects—

(a) Hebb emphasized that the presence of diseased tissue may be more productive of symptoms than the mere absence of cerebral tissue (1939). Several findings are consistent with this view (Roberts, 1951; Fox and German, 1935; Morrell *et al.*, 1956; Nielsen and Raney, 1939; Kreuger *et al.*, 1954).

(b) Most of the marked changes in intellectual functioning are apt to occur with cerebral neoplasm, but this is not essential to produce such deficits (Battersby, Krieger, Pollack and Bender, 1953).

(c) The size of a lesion or its concentration is not the only important factor in producing symptoms (Hebb, 1945) and lesions apparently similar in most respects may result in different disturbances (Dandy, 1933).

(d) Psychological deficits may vary in accordance with the length of time a lesion has existed. The importance of differences with respect to this factor has been stressed by some authors (Karl and Elvidge, 1955; Bailey, 1955), and it has been pointed out that inconsistencies in findings on some psychological tests may be attributed to vast differences in the samples used with regard to the nature and duration of lesions (Battersby, Bender and Teuber, 1951b; Teuber and Mishkin, 1954).

The findings reported by Forgy (1952a; 1952b) are of particular importance in this connexion. He showed that no loss of function was detected immediately after cerebral injury in man, and in the rat, but that some time later there were delayed disturbances, while a partial or complete recovery from deficits occurred in a few weeks' time without special training.

Individual Differences

Another possible source of error may be due to individual differences in anatomical, physiological, and psychological organization and functioning of the brain—

(a) It is well known that brains differ from individual to individual in size and weight. Such variations have been noted with regard to particular lobes.

(b) Investigations of the dominant temporal lobe functions by means of electrical stimulation and lobectomies of various size indicate variations in clinical, electrographic and psychological functions according to *locus* (Pampiglione and Falconer, 1956; Penfield and Rasmussen, 1950; Meyer, 1959; Falconer *et al.*, 1955; Penfield, 1954).

(c) According to Klebanoff (1954), the literature on brain-damaged children suggests that they show more diffuse effects than brain-damaged adults. This may be due to an incomplete differentiation and integration of the cerebral organization and psychological functioning in children. Thus, greater compensation can occur through maturation, whereas in adults damage usually produces more lasting effects. It will be remembered that Hebb (1949; 1942), on the other hand, maintains that a damage to the child's brain has much greater effect on subsequent generalized intellectual functioning than a similar injury to the adult brain.

(d) Considerable amount of evidence shows that right-handers and left-handers differ in the cortical organization for language functions, and that children resemble left-handers in this respect. The notion that aphasia results from lesions of the dominant hemisphere as is indicated by contralateral handedness is undisputed with regard to clear-cut right-handed adults, but in the case of left-handed adults, and in the case of children, this rule does not apply (Hécaen and Piercy, 1956; Humphrey and Zangwill, 1952; Goodglass and Quadfasel, 1954; Roberts, 1955; Etlinger *et al.*, 1956). On the whole, there are more left-brain speakers than right-handers (Goodglass and Quadfasel, 1954; Etlinger *et al.*, 1956). The incidence and the persistence of language disturbances following unilateral lesions in left-handed

adults and in children, compared with the incidence and persistence in right-handed adults, strongly suggests that the former individuals lack fully developed dominance or specialization of one hemisphere for language functions.

Apart from this, it appears that one type of aphasia may occur more frequently in left-handers and another type of aphasia may be more common in right-handers (Hécaen and Piercy, 1956). Also, there is no fixed laterality for all functions and the laterality for speech and handedness does not determine the laterality for other functions (Goodglass and Quadfasel, 1954).

(e) According to Nielsen (1946), the extent to which the non-dominant hemisphere can recover the lost activity of the dominant hemisphere depends on individual differences in age, general health, the suddenness with which the major side fails, and potential. The older the patient, the more sudden the failure, the poorer the general health, and the greater the potential for language functions in the major side, the lower the chances for recovery to take place.

(f) Nielsen (1946) has pointed out that it is possible to find two different individuals with apparently identical lesions, confined to precisely the same area, who will manifest dissimilar after-effects due to different methods of training in acquisition of a particular ability. Conversely, differently localized lesions in two different individuals may produce identical disturbances due to the different level of development and the usage of abilities and modalities.

(g) The magnitude and even the direction of the previously discussed verbal-performance discrepancy, associated with left- and right-hemisphere lesions, may depend on the constitutional predisposition to have one ability "higher" than the other, on the educational background, and on the age of a patient. For instance, it has been demonstrated that the level of vocabulary and the level of non-verbal reasoning ability increase and decrease at different rates with age (Foulds and Raven, 1948); also, the median difference between Performance and Verbal I.Q.s of the Wechsler test varies with age and with the levels of I.Q.s (Wechsler, 1944).

The evidence adduced above argues against classifying brain-damaged cases together indiscriminately, against treating them as a homogeneous group and accepting findings uncritically.

Difficulties and Errors in the Interpretation of Results

One of the greatest failings in psychological studies on localization of functions is the lack of appreciation of the complexity of the problem and the misuse of the

terms and concepts referring to cortical regions and to the nature of the dependence of functions on cortical areas (Osgood, 1953, pp. 475-477).

(a) It must be realized that the various regions of the brain do not constitute functional subdivisions in any sense. The lobes were originally named after the cranial bones under which they lie and as such represent a crude anatomical classification (Bailey, 1955).

The hypothesis that structural differences are correlated with functional specialization has not been supported. Dissimilar psychological functions do not necessarily imply architectonic differences (Lashley and Clark, 1946). The main difficulty with this hypothesis is that while histological studies of the cerebral cortex are in general agreement and show certain areas to be different with respect to histological organization, attempts to subdivide these regions have resulted in many different maps and a cleavage of opinions on various problems (Scholl, 1956, pp. 11-28).

Theoretically speaking, a "functional region" would refer to an area of the brain within which various parts are equivalent with respect to functional specialization. Practicing neurologists refer to functional regions in this sense. (In passing, it can be seen that if one defines a functional region in this way, then Lashley's statement of principle, that within a functional region the cortical cells are equipotential, is tautological.) All that is known is that there are small portions of the cortex which are mainly associated with the arrival of sensory impulses and others which are mainly concerned with the initiation of motor impulses. No other functional specialization can be ascribed to the remaining parts of the cortex subdivided into lobes or on the basis of histological organization, and no functional regions, as defined above, have been conclusively determined.

(b) In attempts to ascribe the possession of certain behavioural characteristics to the integrity of a specific part of the brain the pertinence of Jackson's dictum: "To locate damage which destroys speech and to localize speech are two different things" (Jackson, 1932, p. 130) is often overlooked.

It is commonly agreed that a function is "localized" when its permanent loss follows upon the focal damage of some circumscribed area of the brain, but such evidence does not prove that this area is a component which in any sense "contains" this function, but merely shows that this part of the neural connexions is essential for the behaviour concerned to occur. It is not legitimate to argue that a behavioural characteristic is represented in a region, centre, or spot (Penfield, and Jasper, 1954,

p. 240). It is clear that when the term localization is defined in this way, no function has been conclusively localized. In the first place, complete loss of function has seldom been reported, and in the second, there is a great deal of evidence to show that the cortex has an immense capacity to recover. In this connexion one should bear in mind Jackson's doctrine of deficiency and release phenomena relevant to lesions of the central nervous system (Jackson, 1932).

(c) It is presumed that, when a function whose loss is demonstrated over varying intervals after well-defined, localized damage, can be recovered by retraining, the first area is not essential for this function and some other area can take over the lost function (vicarious functioning of one area for another).

In order to trace the region of vicarious functioning one would have to demonstrate that damage to another area eliminates the possibility of retraining. This inference about brain functioning has been drawn from animal studies and there is no experimental evidence derived from human material either to support it or to reject it. It appears that language functions can be taken over by the non-dominant hemisphere, but such transfer does not occur as a rule, and there is little evidence of true substitution of function in the right hemisphere (Nielsen, 1946).

(d) If no loss of a given function can be elicited following an injury, it does not necessarily imply that this function is completely independent of the injured area. The function may be simultaneously organized in another area (replication of function), hence an injury to either region does not result in a loss. To show that the function is replicated one would require to demonstrate that damage to both regions results in a loss of the function. Here again, there is lack of experimental evidence from human material to support this inference.

(e) If the possibility of equipotentiality and mass action is to be verified, the *locus* and magnitude of the damage should be deliberately varied from subject to subject. Such experimental data from human subjects are lacking.

(f) Further difficulty in the experimental analysis of cerebral mechanisms arises from the fact that some functions, initially lost, particularly after lesions of sudden onset, manifest spontaneous recovery.

According to the theory of diaschisis (Monakow, 1914) a damaged area, not essential for a certain function, may withdraw facilitation from some other cortical or subcortical region, and so result in inadequate functioning of these regions. It is assumed

that the area subject to the effects of diaschisis recovers in time and the lost function reappears spontaneously without training. Forga's results (1952a; 1952b) appear to support the plausibility of this theory. He argued that the delayed disturbances could not be explained by the loss of cerebral tissue nor could the recovery take place through vicarious functioning. The deficits were most probably due to secondary pathological changes produced by the original injury. This study clearly illustrates that in order to arrive at valid experimental analysis of cerebral mechanisms, longitudinal assessment should be carried out and that one must make sure that no retraining has occurred between the testing periods.

It can be seen, therefore, that the complexity of the problem requires a rigorous experimental approach. Studies on human material do not show such an approach and most of the conclusions are not warranted by the data.

Flaws in Psychological Studies

CONTROLS

One of the most serious weaknesses in psychological investigations is the lack or misuse of control data. The premorbid level of psychological abilities is very rarely known; therefore, in order to detect the defective performance of a brain-damaged subject one requires data from normal controls. Evidence has been adduced to show that it is particularly dangerous to use unstandardized tests and to assume a "norm" for the normal population (Hebb, 1945; Pearson and Alpers, 1928; Shapiro and Nelson, 1955).

The nature of the problem under investigation determines what kind of controls are required. If the purpose is to determine the effects of a brain injury on a psychological test one must establish the level of performance on this test for normal subjects. Even if the aim is to assess the effects of a brain operation, normal controls must be tested and retested in the same way as patients, since the conditions, for which patients are being operated on, affect their pre-operative scores. Apart from that, test-retest data on normal subjects are essential for the adequate evaluation of results. If one wishes to find out whether one kind of injury is more effective than another in producing deficits, one must use clinical controls in addition to normal controls. Here again, the problem will determine what brain-damaged controls are needed. Those who study localization of functions and who design brain-damage tests must include a representative sample of brain-damaged population and normal controls; in the latter type of study psychiatric clinical groups should also be included.

Whatever controls are being used must be equated

on any variable which might affect the test scores under investigation. The importance of the age factor is obvious, since various mental abilities decline with age (Gilbert, 1935; Wechsler, 1944; Shaie *et al.*, 1953; Strother *et al.*, 1957). Differences in intelligence can affect performance on various tasks differentially (Boyd, 1949; Beech, 1957). Beech (1957) reported that performance on a perceptual task was radically changed when allowance was made for the initial differences in intelligence. Also, the more intelligent brain-damaged patients were able to compensate for disabilities.

Other relevant factors have been referred to in the previous sections of the chapter.

NATURE OF DEFICITS

Most conclusions with regard to the effect of brain injuries or localization of functions are of doubtful value, since investigators have been preoccupied with demonstrating test deficits and ascribing them to specific lesions in given areas without proceeding to the analysis of the altered functions. As Teuber (1955) pointed out, the tendency is to stop when the "where" is discovered and the question of "what" to localize is left unanswered.

It must be realized that psychological tests are not pure measures of ability. Many of them involve primary motor and sensory functions and a variety of higher mental abilities difficult to define. Thus, performance on a test may be disrupted by cerebral lesions in different parts of the brain for different reasons (Zangwill, 1954; Williams and Pennybacker, 1954). Differently localized lesions may selectively impair different abilities involved in a test. To discover the "whereabouts" of localization, in the sense of damage to tissue disrupting test performance, cannot be regarded as a substitute for the analysis of abilities involved in test performance (Teuber and Weinstein, 1954). If the nature of a deficit is not precisely defined by a careful investigation, the only valid conclusion is that a lesion produces some complex dysfunction resulting in impairment on a test.

In order to determine why a patient failed on a test, or "what" to localize, one must analyse the nature of a deficit, taking into consideration any behavioural aspect which might affect test performance. There is evidence to show that if a test deficit is not analysed, wrong conclusions can be drawn with regard to the nature of impairment (Meyer and Yates, 1955; Semmes *et al.*, 1955; Meyer 1959) and with regard to localization (Weinstein, *et al.*, 1956). Several investigators indicate that impairments on various tasks may be related to various concomitant alterations of functions, e.g. somato-sensory (Weinstein, 1954; Weinstein *et al.*, 1955; Weinstein, 1955a; Ghent *et al.*, 1955a), aphasia (Weinstein *et al.*, 1955; Teuber and Weinstein, 1956;

Meyer, 1959), and epilepsy (Ghent *et al.*, 1955a). Teuber's critical discussion (1955) of some animal and human studies shows that impairments following lesions in primary projection systems and so-called "association" areas are misleading as descriptions of the nature of underlying dysfunctions. He points out that one form of proof required to distinguish between, for example, a "hierarchy of functions" and "separate localization" needs the demonstration of a "double dissociation." Thus, it would have to be shown that, (a) one lesion might cause disturbance of a specific function in one modality without affecting this function as it is executed in other modalities; (b) that another lesion could disrupt the same function in other modalities without affecting its execution through the first.

EMPIRICAL APPROACH

The most common approach to the problem of brain damage is an empirical one. Such an approach is insensitive in the detection of deficits and in clarifying their nature. The lack of any hypothesis prevents the investigator from making deductions, constructing specific tests or using adequate experimental methods.

The literature on brain damage is abundant in information which can lead, if not to clear-cut hypotheses, at least to certain broad expectations.

STATISTICAL ANALYSIS

Frequently reports are inadequate in so far as the need for statistical tests of significance is ignored.

Concept of Brain Damage

Before the characteristics of any group can be explored, the criteria for the selection of the group must be clearly defined. It is commonly agreed that the only criterion of importance which determines whether or not a person is brain-damaged is the absence of cerebral tissue or the presence of pathological tissue. While such a definition is acceptable since it decides which people are brain-damaged, it has certain serious limitations. These have been thoroughly discussed elsewhere (Meyer, 1957) and only the salient points will be mentioned here—

(a) It must be realized that in the majority of cases pathology of the brain can only be inferred indirectly by various techniques. Each discipline has a specific concept of brain damage limited by the nature of its investigatory technique. The validity

of diagnosis derived from each discipline is far from being perfect and the correspondence as to diagnosis is not very high. Psychologists rely on a final neurological diagnosis when selecting cases for investigation; this partly explains why psychological tests of brain damage show such a high degree of misclassification.

(b) As applied clinically, the definition given above has a descriptive, classificatory connotation without diagnostic implication. It groups together indiscriminately a vast variety of patients. The clinician is interested in diagnosis which implies aetiology, nature, *locus* of lesion, and prognosis.

(c) It refers in its scope to people with brain pathologies only and does not have regard to symptoms. Clinical knowledge of brain-damage cases and the test results characterizing them refer to cases with brain pathologies and symptoms.

(d) The emphasis on the importance of brain pathology as the only factor in producing symptoms is no longer fully acceptable. A high proportion of the "normal population" manifests certain abnormalities indicative of brain pathology (Busse *et al.*, 1956; Hill and Watterson, 1942; Williams, 1941). Certain pathologies have been shown to be neither the sole cause nor the sufficient condition for obtaining certain modifications of behaviour (Battersby *et al.*, 1956; Rothschild, 1945; Crome, 1955).

(e) The original definition implies a dichotomous qualitative difference between persons with and without brain pathology. In view of the fact that as the techniques and methods of ascertaining brain pathologies improve more cases are found to exhibit changes (Pampiglione and Kerridge, 1956), it is possible that eventually the alternative view of continuity based on quantitative differences will have to be accepted. Such a view has been expressed with regard to psychiatric diagnosis (Eysenck, 1955c).

(f) Since it is possible that brain pathology *per se* is not a relevant factor, and since it may not be a qualitatively differentiating variable, there is no point in attempting to ascertain its presence or absence alone. Instead, one should attempt to estimate its amount and to discover to what extent anatomic factors and, as Rothschild says (1945), "broader biologic or more personal factors" contribute to the appearance of symptoms.

CONCLUSIONS AND SUGGESTIONS FOR A MORE FRUITFUL APPROACH

The evidence presented does not enable this survey to be concluded with a clear-cut statement of definite principles with regard to brain functioning and organi-

zation. Neither the strictly "departmental" nor the strictly "unitary" views in their present form have been conclusively supported by experimental data. One

finds the greatest support for the theory of "regional equipotentiality" in many psychological functions, but no one has conclusively and precisely established the dependence of any function on any brain region.

The field is abundant in isolated and disconnected studies which do not permit clear orientation. Closer examination reveals that frequent inconsistencies and contradictions may be only apparent and may be correctly interpreted as divergent findings which are due to differences in the samples used with regard to such factors as age of patients, age and type of injury and precise *locus* of lesions. They may be due also to the different tests, testing procedures and evaluation techniques. Various discrepancies, in fact, themselves suggest further lines of research which would throw light on the relevance of various factors.

The perennial controversy between the specific and general effects of lesions has not been settled conclusively. It may be that some general effects reported (Battersby, Krieger and Bender, 1953; Battersby, Krieger, Pollack and Bender, 1953; Bauer and Becka, 1954; Semmes *et al.*, 1954; Battersby *et al.*, 1955; Guthrie *et al.*, 1955a, 1955b; Weider *et al.*, 1955; Ghent *et al.*, 1955a; Teuber and Weinstein, 1956) are due to the complexity of the tasks employed. Adequate test performance depends on a number of different functions; any lesion may lead to a significant test impairment through disturbance of any of the functions involved in a test and for different reasons. Conversely, some underlying generalized effect may account partly for the appearance of specific effects. At the present stage of knowledge, exclusive preference should not be given to the notion either of general or of specific effects, since the nature of deficits has not been analysed (Teuber, 1955; Teuber and Weinstein, 1956).

A similar controversy between "specificity" and "generality" once prevailed in the field of intelligence and personality testing. The evidence based on factorial analysis supports a hierarchical view of cognitive factors (Vernon, 1950) and personality factors (Eysenck, 1947; 1952). It is plausible to postulate then that the functioning of the brain is also arranged in a hierarchical way. This view is supported by results, reported by Teuber and Weinstein (1955), which present a hierarchical finding for visual performance. Lesions which produce focal changes within the visual system also affect certain functions throughout this system, and the latter alterations are accompanied by more general deficits which occur irrespective of the *locus* of injury.

It is the writer's opinion that the first question to be answered is to what degree the effects of brain lesions are general and to what degree specific. Careful study of correlations between behavioural and neurological facts is both essential and basic to the development of a psychological theory of brain

functioning. This could be achieved by a study which would include a representative sample of brain-damaged patients and a sample of normal controls. The brain-damaged group should be given a large battery of tests which are known to be measures of well-defined orectic and cognitive factors. The results should be submitted to factorial analysis. In the next stage, more refined tests designed to assess the extracted factors should be administered to both the organic and the normal control groups. The results should be submitted to analysis of variance and the performance of each subgroup (subdivided according to the *locus* of the lesion) should be analysed in relation to those of the controls and of a complementary subgroup consisting, in each case, of the remainder of the brain-damaged group. Similar studies should be carried out on children of various age levels in order to define the nature of developmental aspects of brain organization and functioning. The use of large groups with variously localized lesions and the employment of statistical analysis will to some extent overcome the difficulty in the precise localization of lesions. In a number of studies, in an attempt to localize various functions, analysis of variance technique has been employed (Battersby *et al.*, 1955; Teuber and Weinstein, 1954; Semmes *et al.*, 1954; Weinstein and Teuber, 1957; Teuber and Weinstein, 1956; Semmes *et al.*, 1955; Weinstein *et al.*, 1956).

However, it would not be sufficient to stop at mere correlations and the research should proceed to clarify their significance. This would require an extensive and intensive study of the nature of each significant association between factors and *loci* of damage, controlling for all the relevant variables including the neurological mechanisms responsible for the negative and positive properties of functions. Such an approach would throw light on the nature of normal behaviour in the intact organism and it would also bring about co-ordination between neurology and psychology. What is most important, it would permit the development of a precise psychological theory on the basis of which sensitive diagnostic tests of brain damage could be constructed. Attempts to construct diagnostic tools at the present stage of knowledge are premature and doomed to failure. Eysenck (1955b; 1957) has demonstrated, in the field of personality, how an intensive study of statistically derived personality factors can be used to enable one to arrive at an explanatory theory to account for their existence.

It would appear that the clinical psychologist's contributions to the everyday problems of a clinic must be minimal if he lacks proper diagnostic tools, but the psychologist should never stress the diagnostic aspect of his work *alone*. Although the discovery of a lesion and its *locus* has important bearings on diagnostic and prognostic implications,

in itself it does not explain the appearance of symptoms or elucidate the neurological mechanisms responsible for such behaviour (Skinner, 1938, p. 424).

The psychologist's main aim, as a student of behaviour, is to detect deficiencies, formulate explanations to account for them, and to test the deductions arising from his explanations. Such a method of investigation would lead to a thorough understanding of the patient's abnormality and, with the information available, an attempt could be made to retrain the patient. Such an approach has been applied to individual psychiatric cases (Shapiro and Nelson, 1955; Shapiro, 1951*b*; Payne, 1953). Some workers have demonstrated that brain-damaged patients are not necessarily passive carriers of morbid anatomical processes which have irreversible consequences; using acceptable theories to account for an abnormality, they designed successful treatment techniques (Schuell, 1953; Schuell *et al.*, 1955; Birch and Lee, 1955; Efron, 1957).

Some of the clinical psychologist's findings will provide data for further fundamental research, and some of his results will be incorporated in the development of the theory of brain organization and functioning; but no matter how far fundamental research progresses, the clinical approach to individual cases is still likely to be of value. There are subtle individual differences which will still necessitate careful and precise investigation of each case on its own merit for the purposes of treatment and disposal.

In all types of work the clinical psychologist must bear in mind that, as in fundamental research, he will be of use precisely to the extent to which he can bring his training in scientific method and his knowledge of psychological principles to bear on the problems of the clinic.

CHAPTER 15

The Effects of Psychosurgical Procedures on Behaviour

R. A. WILLETT

INTRODUCTION

In a review which has become something of a classic, Hebb (1945) concludes that cerebral functions cannot be inferred from the observation of behavioural abnormalities accompanying tissue damage that has resulted from either trauma or disease processes. In these cases, he argues, the crucial information as to the extent and site of the lesion and its secondary effects is lacking and, he continues, can only be supplied where surgical lesions have been introduced into an otherwise intact cerebrum. Chow and Hutt (1953) have insisted on even more stringent control of these two variables, demanding in their review of the related work on *macaca mulata*, that only studies giving full histological details be accorded serious consideration in the identification of cerebral functions.

Such requirements as these can rarely be met in human subjects but the best approximation is certainly to be found in the various psychosurgical procedures carried out for the relief of psychiatric illnesses. Although, indeed, a number of neuro-pathological studies (Dax and Radley-Smith, 1943; Dax *et al.*, 1946; Greenwood, 1948; Mettler and Rowland, 1948; Yakovlev *et al.*, in Greenblatt *et al.*, 1950; Eie, 1954; Meyer and Beck, 1954 and Yokoi, 1957) have demonstrated that psychosurgical lesions tend to be inaccurately placed and their secondary degenerative effect widespread, we have considered that the measure of control, afforded by these techniques, warranted a treatment separate from that of "natural" brain damage, the aberrant condition dealt with in the preceding chapter.

Before coming to our review, several points of policy should be noted. Firstly, we shall use the term prefrontal leucotomy (or simply leucotomy) as that proper to describe procedures aimed at introducing lesions into the white matter of the frontal lobes. Where neurosurgically different techniques have been employed, terms, descriptive of the site or nature of

the lesions, as commonly found in the literature, will be used. Since all these surgical procedures have the common purpose of relieving psychiatric illnesses, the term in current use, psychosurgery, is adequate to describe them all and will be employed as the appropriate generic term throughout this review. "Lobotomy," although very frequently used in the literature in this connexion, is a misnomer and should be eschewed. Secondly, we have chosen Brodmann's reference system (1909) against the claims of more recent systems (e.g. Economo and Koskinas, 1925) as being that most frequently encountered in the literature.

Thirdly, our concern is with experimental studies and, from a consideration of the data that they provide, we shall see how far we can go towards presenting a coherent picture of the effects of psychosurgery on behaviour, and towards drawing substantial inferences about frontal lobe functions and their relationships to behaviour. While being aware of the objections to extrapolating from infra-human studies to human behaviour, we have regarded the data collected from these sources as having important implications for human studies and as being derived under conditions of experimental rigour which are probably optimal in the field. Just because of the difficulties arising in generalizing from one phylogenetic level to another, however, we have largely confined ourselves to studies on infra-human primates where physiological and neurological differences are probably minimal.

Finally, because we are primarily concerned with experimental data, we shall be minimally occupied with clinical reports where neither control observations nor objective measures have been employed. We have considered it a secondary purpose of our review to assess the therapeutic efficacy and rationale of psychosurgical procedures but, since we regard most of the reports that would usually be taken as

central for such an assessment as being deficient in regard to both control observations and objectivity, our treatment of these topics may appear cavalier. The value of subjective uncontrolled clinical reports

is that of all other raw observation; they are the source of hunches, hypotheses that lead to experimental and controlled observations and the elaboration of theories.

PSYCHOSURGERY: SOME GENERAL COMMENTS AND SUMMARY OF CLINICAL OBSERVATIONS

General Comments

The history of psychosurgery has been recounted too often before (Freeman and Watts, 1950; Greenblatt *et al.*, 1950; Fisher, in Walker, 1951; Fulton 1951; Kalinowsky and Hoch, 1952) to be repeated here in any detail but a curious set of circumstances surrounding its reputed beginnings requires some comment.

Tradition has it that Egas Moniz, the noted Portuguese neurologist, conceived of the possibility of the operation as a treatment of psychiatric disorders after listening to papers by Brickner (1936) and by Fulton and Jacobsen (1935—*see also* Jacobsen, 1935; Crawford *et al.*, 1947). The latter writers described the disappearance of experimental "neuroses" in two chimpanzees who had suffered extensive damage to the frontal areas. Brickner had given preliminary comments upon the behaviour and intellectual status of a single patient who had been subjected to extensive ablation of the frontal areas for the removal of a tumour. Now, if these papers did in fact suggest the possibility of a therapeutic surgical procedure at first, examination of the evidence, even slightly less than superficially, should have dispelled the idea at once.

In the first place, like procedures had been tried before without signal success (Burckhardt, 1890) and in the second, a closer consideration of the data upon which these papers were based would have revealed no grounds for encouragement. Jacobsen (1935), reporting on his and Fulton's observation, was at some pains to distinguish the rather restricted phenomenon of experimental neuroses from the equivalent term applied to psychiatric patients.¹ Moreover, the main burden of his and Fulton's paper was that a serious "intellectual" deficit followed frontal ablations in the chimpanzee observed.

Brickner reported on a single case, without having had the benefit of pre-operative assessments; for these crucial data he substituted the uncorroborated statements of the patient's relatives and friends. Basing himself on these and his own post-operative observations, he characterized the change in his patient in terms which were certainly mild enough to be reassuring but which, in fact, hardly represented

the gross aberrations in behaviour and cognition which his own protocols reveal (Brickner, 1936). So contrary are the indications for psychosurgery to be derived from these sources that one doubts the accuracy of the whole story. Moniz (1954) himself has relegated the influence of these papers to that of merely crystallizing certain ideas along lines he had already adumbrated at the time and, when one considers the matter, this does not seem unlikely. One cannot avoid the speculation that, at the time of the introduction of psychosurgery, psychiatry was ripe for a new therapeutic panacea and that, for a time at least, these procedures, enthusiastically espoused by a few workers at first, quickly took on the appearance of affording such a panacea.

Moniz's conception was not to reproduce the massive lesions effected in either the chimpanzee or Brickner's patient but to effect relatively circumscribed interruptions in the corticothalamic tracts in the frontal lobes. This has remained the basic aim of most later leucotomies and psychosurgical procedures.

These procedures have become very numerous indeed and, although it is not our business to trace their development in any detail, we shall have to mention some of the main innovations. Figs. 15.1 and 15.2, show diagrammatically the purposed lesion sites of some of the more commonly used techniques. More extensive descriptions than those intended here will be found in the original papers quoted and in Crook *et al.* (1949), and Kolb (1949), Fairman (in Greenblatt *et al.*, 1950), Fulton (1951), Kalinowsky and Hoch (1952), Otenasek (1953), Le Beau (1954) and Schurr (1956).

As first used by Moniz (1936*a* and *b*) and the surgeon Lima the operation consisted of the destruction of corticothalamic pathways by the injection of alcohol through burr holes. This form of the operation was not retained for long, although proponents of it have reappeared from time to time (Fernandez-Moran, 1946; Soupault, 1954; Soupault and Bucaille, 1955). Moniz and Lima themselves replaced it by a procedure in which a "core" of tissue was removed by a special instrument, the leucotome, which they developed. It is interesting to note that the long-term assessment of these early operations has been unfavourable (Furtado, 1949) but before any results could be properly assessed the procedure was applied,

¹ A comprehensive critique of the concept of experimental "neuroses" will be found in Chapter 19 of this HANDBOOK, by P. L. Broadhurst.

with various modifications in Italy (Rizzatti, 1937; Rizzatti and Borgarello, 1938; Fiamberti, 1937), Switzerland (Ody, 1938), America (Lyerly, 1939; Freeman and Watts, 1942, 1950) and England (McGregor and Crumie, 1941).

(Adapted from Meyer and Beck, 1954)

Undoubtedly the greatest impetus to the new psychosurgical procedures was given by the work of Freeman and Watts (1942, 1950) in America. Their original technique, the so-called standard lobotomy, is the basic operation from which most of the others have developed and, as can be seen from Figs. 15.1 and 15.2, was a relatively extensive procedure. Despite the enthusiasm of these two workers, this form of the operation also lost favour as various unfortunate *sequelae*, such as apathy, irresponsibility,

lack of initiative and energy, not to mention the commonly recorded high incidence of post-operative seizures, began to be reported (Rosenblum *et al.*, 1955; Walker *et al.*, in Thompson, 1955; Paul *et al.*, 1957). Moreover, the operation tended to be time-consuming in relation to the number of patients Freeman thought could benefit from it (in Thompson, 1955) and also—a serious practical consideration—patients treated by standard lobotomy frequently presented serious nursing problems for already understaffed hospitals in the immediate post-operative period (Freeman and Watts, 1942, 1950). Consequently, much of the more recent history of psychosurgery reduces to the establishment and investigation of new surgical procedures aimed at limiting the

(Adapted from Meyer and Beck, 1954)

supposed negative *sequelae* of standard lobotomy whilst retaining its reputed benefits.

At the present time almost every major neurosurgeon in the field has his own version of a selective procedure, as the more circumscribed forms of psychosurgery have come to be called. Freeman

(1948, 1949) himself proposed transorbital lobotomy based on the pioneer work of Fiamberti (1937) in Italy. This technique differed from all others in that it involved no broaching of the cranium, an instrument being introduced into the orbital surface of the frontal cortex via the orbital plate, above the eyeball (Jones and Shanklin, 1950; Moore and Winkelman, 1950). The special advantages of this technique commonly claimed are, speed and facility (Freeman, 1948, 1949; Freeman *et al.*, 1954) and safety with fewer negative *sequelae* (Jones and Shanklin, 1950; Moore and Winkelman, 1950; Freyhan, 1954). Gardner (1957) has gone so far as to recommend the use of transorbital lobotomy in private practice.

Other modifications were introduced by Lyerly (1939)—Poppen (1948) has employed Lyerly's technique widely—Scoville (1949) and Scoville *et al.* (1951), McKissock (1951) and Grantham (1951). Both Pool (1951; Pool *et al.*, 1949) and Le Beau (1954) have been notable exponents of modified psychosurgical procedures and have introduced important variants of their own. Spiegel and Wycis *et al.* (1948), on the basis of their hypothesis that degeneration of the mediodorsal nucleus is largely responsible for the reported effects of psychosurgery, interrupt the corticothalamic tracts by stereotactic coagulation of the thalamic nuclei. Lindstrom (1954) and Fry (1956) have reported the production of very precise lesions by means of ultrasonic irradiation.

Again, because we do not wish to be led too far from our main path we shall not go into the various rationales for these separate procedures. One should note in passing, however, that frequently surgeons appear to have been prompted by hunches and empirical experience rather than by any clearly formulated hypotheses when proposing their various modifications. A number of accounts have been suggested for the effects of psychosurgery and these we shall briefly outline. They tend to be *ad hoc*, speculative and difficult to either prove or refute. Indeed, one is tempted to hazard the suggestion that few surgical procedures can be based on such tenuous grounds as those of psychosurgery.

Moniz (1936a), originally suggested that in mental illnesses, groups of cells formed abnormal "circuits" in the frontal lobes and became set in their patterns of activity so that the patient's associations became characteristically pathological. He therefore argued that the dysfunctioning frontal lobes should be severed from their connexions with the thalamus (regarded as the centre for the initiation of emotional responses) and thus isolated. Variants of this rationale for the operation have usually formed at least the core of later formulations.

Greenblatt and Solomon (1953b) for example, conceive that frontal lobe circuits, operating in a positive

feed-back fashion, are the mechanisms sustaining emotional tension in psychotic individuals. The effect of psychosurgery is thus to cause great reductions in the cells and circuits of the frontal lobes, thereby reducing tension and the debilitating symptoms.

Puech *et al.* (1950)¹ summarize the views of a number of French writers whose notions share much in common with these better known formulations. Feuillet and Collin are quoted as writing—

Pathological structures . . . suffer the same type of dissolution as the neuro-psychical edifice by which they are mediated. Their freed elements, at the time of the reorganization that follows, take their place in the plan of the whole, that of normal integration . . . surgical intervention could amount simply to the reduction of the active cerebral surface and, by this means, of its capacity to synthesize; this being in line with those authors like Lashley who posit a large degree of functional equipotentiality in the cortex. Certain facts give credence to such a quantitative factor; it is thus that the effects of lobotomy are more severe when carried out with varying cuts—larger or more posterior lesions increasing the area affected.

Sanchez and Camancho are quoted in the following terms—

Lobotomy isolates a great area of intra-cerebral connexions; the remaining cortex being deprived of this area is forced to adapt new neuro-physical experiences to a new system of functional relationships.

Finally, Delay is quoted in these terms—

The commonly found effects of leucotomy, particularly in the emotional sphere, can be explained by changes of cortico-basal interactions—between the frontal cortex on the one hand and the thalamus on the other and not so much the activity of the latter as such as in its role as a relay for the hypothalamic-hypophyseal tract of the diencephalon.

A number of other such hypotheses have been offered. Greenblatt *et al.* (1950), for example, quote Cobb as also suggesting that leucotomy interferes with long circuiting.

One can note two main themes running through these speculations—a quantitative reductive factor being regarded as the principal determinant of change on the one hand and one of reformation of "circuits" or cell constellations on the other. Beyond such a comment it is not possible to go with these ideas. They presuppose the resolution of most of the problems besetting the neurology of the central nervous system, which resolution, as Meyer (Chapter 14) has pointed out, has by no means been achieved.

Hebb (1949) has offered an hypothesis rather different from these and one which is far more

¹ The writer is entirely responsible for any misrepresentation of these views through errors in translation.

TABLE XV.1
SELECTION OF CLINICAL STUDIES

Authors	Year	N	Type of patient	Operation	Problem of study	Findings and conclusions
Berliner <i>et al.</i>	1945	100	Chronic psychotics	Standard lobotomy	Clinical survey	Need for re-education stressed; good results with obsessional, melancholics and schizophrenia.
McKenzie and Proctor	1946	27	Mixed psychotics and neurotic cases	Standard lobotomy	Clinical survey	Report 50 per cent social recovery rate; a mild hypersexuality noted in 25 per cent of cases.
Van Wagenen	1946	30	Mixed diagnoses	Standard lobotomy and corpus callosum lesions	Efficacy of lobotomy	Lobotomy relieves states of tension and depression. Result not achieved by dividing association fibres of corpus callosum.
Oltman <i>et al.</i>	1948	107	85 per cent schizophrenic diagnoses	Lyerly-Poppen type	Clinical survey	56 per cent of patients improved. Improvement rate higher for non-schizophrenic patients.
Rothschild and Kaye	1948	100	Schizophrenic diagnoses	Lyerly-Poppen type	Effects of leucotomy on schizophrenia	42 per cent of patients improved. Changes only superficial. No influence on the basic psychopathological processes.
Reitman, F.	1948	250	Mixed psychotic diagnoses	Various operations including a "low vertical orbital" procedure	Clinical survey and comparison of operations	Orbital procedure more effective. 24 per cent of patients recovered; prognosis poor for deteriorated cases.
Aldrich	1950	10	Mixed diagnoses	Standard lobotomy	Social adjustment in family life	The need for re-education and supervision in the presence of children stressed.
Drubin	1950	62	Psychotic male veterans	Modified standard lobotomy	Clinical survey	37 per cent greatly improved, 56 per cent improved, 7 per cent unimproved.
Edwards	1950	71	Mixed diagnoses	Transorbital lobotomy	Clinical survey	Operation good with anxiety and depression cases; not useful with schizophrenia. Few side-effects noted.
Hoffman	1950	78	Mainly schizophrenic diagnoses	Modified standard lobotomy	Clinical survey	Lobotomy operation of limited value. Should be used only as a last resort.
Lyerly	1950	127	Mixed diagnoses	Lyerly-Poppen type	Clinical survey	76 per cent greatly to moderately improved. 24 per cent unimproved.
Stengel	1950	330	Mixed diagnoses	Various procedures	Clinical survey	The nature and the extent of the change related to extent and site of the lesion and to premorbid personality.
Levine and Albert	1950	<i>See text</i> —subjects and operational procedures from the study by Greenblatt <i>et al.</i> (1950)			Effect of operations on sexual behaviour	No consistent changes noted. Changes related to the role played by anxiety in sex behaviour.
Moore and Winkelman	1950	110	Mixed diagnoses	Transorbital lobotomy	Clinical assessment of operation	Operation good with non-deteriorated psychotics and with psychoneurotic cases. Poor with deteriorated cases.
Johnson and Ehrenberg	1951	80	Mainly schizophrenic diagnoses	Lyerly-Poppen type	To determine the relationship of "reaction type" to improvement	The degree of recovery found to be inversely related to the degree of deterioration pre-operatively.
Pittman <i>et al.</i>	1951	200	Psychotic diagnoses	Standard lobotomy and transorbital lobotomy	Comparison of efficacy of two procedures	Transorbital lobotomy superior; some improvement in 69 per cent of cases.

Sargent	1951	Psychosomatic disorders	Standard lobotomy	Clinical survey	Reduced anxiety in cases suffering from psychosomatic disorders.
Simon <i>et al.</i>	1951	33 Schizophrenic diagnoses	Unilateral and standard lobotomy	Comparison of two procedures	68 per cent of standard operation cases improved; 17 per cent of unilateral operation cases improved.
Worthing <i>et al.</i>	1951	600 Mainly schizophrenic diagnoses	Standard lobotomy	Clinical survey	Operation regarded as useful. 33 per cent of non-schizophrenics returned home.
Bonner <i>et al.</i>	1952	41 Intractable pain	Various procedures	Comparison of operations in pain cases	Standard lobotomy regarded as too drastic for pain cases.
Kane <i>et al.</i>	1952	122 Mixed diagnoses	Modified standard lobotomy	Clinical survey	63 per cent of cases benefited to some degree.
Margolis <i>et al.</i>	1952	13 Mixed psychotic diagnoses	Unilateral leucotomy	Assessment of operation	5 patients much improved; 4 moderately improved; 4 unimproved.
Swartzlander	1952	19 Schizophrenic diagnoses	Standard lobotomy	Clinical survey	Ward behaviour improved. Schizophrenic process unaffected. Some evidence of worsening after operation.
Stevenson and McCausland	1953	22 Recurring manic-depressive illnesses	Standard lobotomy	Effect of operation on the recurrent illness	Four year follow-up showed that the recurrent feature of manic-depressive disorder could be alleviated.
Greenblatt <i>et al.</i>	1954	85 See text—subjects from	Greenblatt <i>et al.</i> 1950	Work adjustment	Work level post-operatively below pre-morbid state.
Hoch <i>et al.</i>	1954	40 Pseudoneurotic schizophrenia	Topectomy, bimedial lobotomy and pre-coronal lobotomy	Clinical survey	88 per cent improved after 36–48 months. Period of "growth" necessary after operation.
Kraft	1955	Mixed diagnoses	Standard lobotomy	Changes in handwriting	No graphological changes noted.
Kral and Elvidge	1955	100 Mainly schizophrenic diagnoses	Bimedial leucotomy	Clinical report	73 per cent showed some improvement. 18 per cent developed seizures but these unrelated to recovery.
Newman	1955	25 Schizophrenic diagnoses	Modified standard lobotomy	Clinical survey	Indifference and lack of drive noticed.
Pippard	1955a	240 85 per cent neurotic and affective disorders; 15 per cent schizophrenic	Rostral leucotomy	Clinical survey	Superficial improvement. No change basic disease process.
Pippard	1955b	120 Non-psychotic diagnoses	Rostral and standard leucotomy	Comparison of the two operations	Improvement with reactive depressions, depressions, involutional melancholia and tension states.
Lane	1956	19 Women, mixed diagnoses	Unspecified	Social adjustment in the family	Little negative personality defect after rostral operation in 95 per cent; none in only 45 per cent after standard operation.
Schwarz	1956	46 Schizophrenic diagnoses	Various operations	Clinical survey	Marital adjustment unchanged. Children disturbed either because of mother's indifference or "changed ways."
Freeman	1957	3,000 Mixed diagnoses	Standard and trans-orbital lobotomy	Clinical survey	After six years, 27 per cent discharged, 73 per cent still in hospital. Operation of minimal value. 70 per cent of schizophrenics, 80 per cent "affective disorders" and 70 per cent of psychoneurotics out of hospital in 5–10 year period. Transorbital lobotomy, found to be safer, more effective, more applicable to the needs of a modern state hospital.

elaborate and closely documented. In essence this hypothesis regards emotional disturbances as consisting of the disorganized firing of neural elements in the cerebral cortex. Leucotomy (or electroconvulsive-shock therapy) produces scar tissue and either this or "deafferentiation" in turn produces a state of hypersynchrony (the predominance of large potential slow waves) in the firing of the cerebral neurons. Such a hypersynchrony would then—

provide a pacemaker . . . that would tend to pick up any neurons that are not incorporated in assembly activities and so substitute the "intrinsic" organization of cortical activity for the diffuse activity of the normal waking adult state.

It can be seen that the verification of this hypothesis is essentially conditional upon the demonstration of a concomitance between hypersynchrony and clinical improvement after psychosurgery. Taking this condition in two parts, it can be stated straight away that ample evidence is available to show that hypersynchrony very frequently follows psychosurgical procedures, which evidence we will outline in a later section dealing with electroencephalographic findings.

That Hebb's account is not entirely satisfactory, however, becomes evident when one considers that hypersynchrony after psychosurgery has been found in patients who have shown no clinical improvement—in the case of schizophrenic patients, for example. In a sense Hebb has allowed for this negative finding. He commences his account by observing, correctly we believe, that where improvement follows psychosurgery, the principal symptoms relieved are states of tension and anxiety and depressions. If these symptoms then comprise the emotional disturbances which consist of the disorganized firing of cerebral neurons, the hypothesis is much more limited in its application but much more defensible. This position also carries with it the not unreasonable implication that other forms of emotional disturbances are of a different nature from those relieved by psychosurgery and the presence of hypersynchrony, post-operatively, would be irrelevant for their course. The disproof of Hebb's hypothesis, would on this view, require that states of tension and anxiety and depressions be relieved without evidence of hypersynchrony in the EEG records. A direct test of the hypothesis, along these lines has not been made but what evidence there is, will be presented in the later section mentioned.

We shall refer to other neurological hypotheses throughout our treatment of the data of psychosurgery but these, having more specific applications will be dealt with severally as the need arises. Likewise, the psychological hypotheses about the action of psychosurgical techniques will be treated separately.

Summary of Clinical Observations

As a preliminary to presenting the objective data with which we are primarily concerned, we wish to summarize the clinical findings of what we regard as a selection of the most reliable studies reported. A basically subjective method of assessment characterizes the studies to be reported here; the relevant sections from large-scale studies, employing objective measures additionally are included, together with animal investigations essentially subjective in method. Table XV.1 sets out examples of the sort of study with which we shall not be concerned, those which largely report the percentages of various categories of patients, judged to have recovered to greater or lesser extents after the operations to which they have been subjected.¹ Usually, these papers provide as well reflections on the functions effected by the procedures and the role played by the frontal lobes in behaviour.

Apart from the major texts in the field (Mettler, 1949, 1952; Lewis *et al.*, 1956; Greenblatt *et al.*, 1950; Greenblatt and Solomon, 1953; Freeman and Watts, 1942, 1950) excellent general reviews of clinical studies have been given by Partridge (1950), Crown (1951), Klebanoff (1945, 1954), Kolb (1949), and Kalinowsky and Hoch (1952). Freeman has provided a number of informative annual reviews of "Psychosurgery" (1951, 1952, 1953, 1954, 1955, 1956, 1957), to which reference can be made for short summaries of clinical results. Furthermore, a number of joint investigatory projects—apart from those we intend to discuss—have appeared and include interesting clinical data. Amongst these, the reports edited by Brigalow (1949), Overholser (1952, 1954) and Miller (1954) are perhaps the most important. Shevchenko (1954) has reported on Russian work in his monograph and presented the Russian view of prefrontal leucotomy.

As is evident from Table XV.1 any reviewer of this material has to face a multiplicity of aims and procedures that bedevils any attempt at generalization and astonishes with the versatility of the procedures and the industry of the investigators. Kolb (1953) brought a little light to bear on one aspect of this obscure complexity when he computed that, up to the date of his writing, the patients who were subjected to psychosurgery comprised: 60 per cent schizophrenics of divers classifications; 25 per cent "affective" disorders and 10 per cent psychoneurotic

¹ Two very relevant papers by Robins (1958, 1959) have appeared and must be mentioned. Robins compared recovery, discharge and remission rates for psychotic and epileptic patients after leucotomy, the subjects of control groups were matched on diagnosis, chronicity, age and sex. He could report no advantage for the leucotomy groups: categories of patients who recovered, recovered equally well in both treated and untreated groups; categories of patients who showed no improvement were equally present in both groups. These studies being well controlled are of the utmost importance.

patients. Even then, Kolb's list leaves out of account certain categories which cut across these psychiatric ones. Psychosurgery has been applied to epileptics (Baretto, Velasco *et al.*, 1949); very frequently for the relief of intractable pain (Scarff, 1948; Freeman and Watts, 1950; Le Beau, 1954); to cases of psychopathy (Kalinowsky and Scarff, 1948; Ackerly in Overholser, 1954); for the relief of affective disorders in old age (Scoville and Ryan, 1955) and has been applied in connexion with tuberculosis (Cheng *et al.*, 1956). The results with some of these dysfunctions—in the cases of epileptic conditions, in psychopathy and disorders in childhood, for example—have generally been regarded as failures (Kalinowsky and Hoch, 1952; Ackerly in Overholser, 1954) and, indeed, it is difficult to see how one procedure could possibly be beneficial for all these conditions and categories of patients, implying, as they frequently do, opposites in symptomatology.

Since the appearance of Freeman and Watts (1942) essentially clinical monograph reporting on their first eighty cases, a number of large-scale investigations have appeared which have included clinical investigations and deserve special mention. Apart from this first and the subsequent second editions of Freeman and Watts *Psychosurgery* (1950), those that we shall deal with are the two reports of the Columbia Greystone Associates (Mettler, 1949, 1952), the allied report of the New York State Associates (Lewis *et al.*, 1956) and the two reports by Greenblatt *et al.* (1950) and Greenblatt and Solomon (1953) from the Boston Psychopathic Hospital. All possess in common a belief in the "blunderbuss" approach, whereby a group of patients are investigated independently by the techniques of many disciplines and relatively discrete reports are presented on the results of the separate investigations. Each investigation, as far as one can make out, is largely empirical, that is, not hypothetico-deductive. Any piece of information concerning the effects of the operation is regarded as worth recording, no matter how unconnected with any other. To a certain extent one can sympathize with this desire for fact-gathering in the early stages of describing a phenomenon but the report of the New York Associates follows exactly the same methodology in most respects as was pursued by the first report of the Columbia Greystone Associates, albeit certain generalizations from the earlier works were followed up. One would have thought that enough random observations on psychosurgery would have been made by this time to encourage the beginnings of a more intensified, coherent and systematic series of studies.

The source reference for the succeeding studies and, in many respects the model for them, is the first edition of *Psychosurgery*, Freeman and Watts's report on

their first eighty cases. The work is entirely clinical in approach but, to a greater degree than the succeeding studies, presents a commendable singleness of purpose. It reports about the same percentage of recoveries as became fashionable after it—about one third being greatly benefited, another third slightly improved and the remainder little, or not improved at all. One further fashion was set in that some attempt was made to characterize the essential nature of the change after the operations, the characterization carrying implications for the nature of frontal lobe functions. The conclusion of this first edition of *Psychosurgery* was that: "Psychosurgery alters the structure of the self through reducing self continuity"—self continuity being, presumably, some awareness of the continuity of oneself through the past, present and future. Hutton (1947) reports a similar interpretation for the changes of ten subjects studied pre- and post-operatively.

The second and greatly expanded edition of the work remains very much the same. Confirmatory clinical results are added but what meagre objective assessment was offered in the first volume is omitted from this second. Freeman makes one further addition when he introduces the technique of Transorbital Lobotomy and presents some preliminary results which, he claims, demonstrate that the method has those advantages we have previously mentioned.

One cannot really assess the worth of these two works by any accepted standards of scientific criticism. They are simply the massive accumulation of uncontrolled observation set out, often, in dramatic layout. A predilection of Freeman's for "before" and "after" photographs is indulged to the full and one senses that the authors' suspicion of objective methods of assessment, evident in the omission in the second edition of Hunt's original chapter on "Psychological Tests," is again reflected in the substituted chapter by Robinson. She describes her method of psychological assessment in the following terms—

The method employed was uncomplicated but laborious and time-consuming. Divesting myself as completely as possible of all theories and preconceptions, I tried passionately to understand each person as I watched him and listened to him talk. Tests were made only to supplement observation. Later I went over my voluminous notes and made comparisons among individuals (in Freeman and Watts *Psychosurgery*, 1950).

The fruition of such "passionate endeavours" and a frequent by-product of many clinical investigations is a post-operative picture of the leucotomized patient. We have thought it fitting to include such a one at the end of this section.

The Columbia Greystone Associates (Mettler, 1949), listing some forty-three contributors in their

first report, examined twenty-four operated patients and twenty-four matched controls. Their primary interest was to gather "information as to whether less drastic and technically improved neurosurgical approaches would produce results as satisfactory, or perhaps better than those obtained by lobotomy." To this end, the subjects selected for operation underwent the more or less circumscribed procedure of topectomy, a more drastic operation being proposed if the patient, within an appropriate interval, showed no improvement after this first.

All patients were psychotic, mainly of various schizophrenic diagnoses, and formed a group which the Associates came to realize was anything but homogeneous. Patients were allocated to the operations, subsumed under the term topectomy, in a non-random fashion as Tizard (1958) has pointed out, although when one considers that there were no less than nineteen operative procedures called topectomy, the randomness or otherwise of distributing twenty-four patients to operations becomes a matter of extremely limited meaning. Clinically the results appeared to be reasonably encouraging, a significantly greater number of operated subjects being rated as "improved" after three months, seven months and one year. Furthermore, the writers believed they had some evidence that areas (Brodmann) "9," "10" and "46" were most closely related to improvement. Finally, they suggested that the circumscribed procedure of topectomy was as effective as standard lobotomy and produced no noticeable deterioration of intellectual functions.

This first report of the Columbia Greystone Associates possesses the failings we pointed out at the beginning of this section to an extreme degree. One is impressed by its parts but perplexed by its almost total lack of coherence in design or use of controlled observations. The second report of these Associates (Mettler, 1952), listing thirty-six contributors (eleven of whom, including Mettler, Landis, Zubin, Curry and the surgeon Pool, were concerned in the first report) criticizes the first on a number of grounds and draws the general conclusion that its findings were unwarranted.

Two most telling criticisms are brought to bear upon the first report. Firstly, it is rightly pointed out that the fewness of the cases in each operative category completely invalidates any suggestion that areas "9," "10" and "46" could be of special importance. Secondly, the prognostic rating scale developed for the second study (the "Rocklands Investigation," Mettler, 1952) was applied to the subjects of the first. It was demonstrated thereby that the control group in the first study had much poorer (pre-operative) prognostic ratings; twelve of them having the lowest ratings and only one the highest, while of the operative

group, twelve had the highest ratings and only one received the lowest. Thus they concluded that it was doubtful whether any of the improvements noted in the operated group could be attributed to the operation—they might as readily have been the result of the higher rate of recovery, likely for the operation group, over the course of time. The criticism does cast a grave doubt on the results of the first report but one must not lose sight of the unreliability of the ratings on prognosis themselves.

In form, the investigation reported in this second monograph of the Columbia Greystone Associates is very similar to the first except that the control of certain variables, particularly with respect to the cases selected, was much more satisfactory. Thirty-three cases comprised the subjects of this study, almost all being schizophrenic in symptomatology and of roughly equal numbers of the hebephrenic, catatonic and paranoid subtypes. Information on the effects of two main operations was obtained, venous ligation (involving the interruption of the blood flow through the superior cerebral veins to the frontal lobes) and transorbital lobotomy (performed by Freeman). In addition to these, two cases were seen who received thalamotomy (Spiegel and Wycis's technique of cauterizing the dorsomedial nuclei of the thalamus) and two were subjected to thermocoagulation of the cerebral cortex, in particular, of areas "9" and "10."¹

Twelve cases were seen who were subjected to venous ligation and nine were subjected to transorbital lobotomy. There were six controls but despite the many refinements introduced one cannot help feeling that a few cases have been again overburdened by the weight of too many operative procedures. The conclusions are more cautious than those of the first report and Mettler and Landis write that in none of the operations they have studied have they been able to demonstrate, unequivocally, any relationships between the psychosurgical procedures and rate of improvement. They consider the two reports together and note that as the period of hospitalization increased (a factor uncontrolled in the first investigation but taken care of in the second) the rate of improvement decreased and they incline to the belief that this factor together with the "total push" technique of post-operative treatment could well account for any improvement found amongst the operated group.

The most recent investigation, reported by many of the principals of the Columbia Greystone studies, is that of the New York Associates in Brain Research (Lewis *et al.*, 1956) whose depleted ranks reach only thirty-one and who can manage only a much slimmer

¹ This procedure was based on the work, of Dusser de Baronne (1935) who demonstrated on monkeys that the application of different degrees of heat would destroy, quite discretely, layers of cortex, more being destroyed as more heat was applied.

volume. Sixty-six patients were seen, divided into subgroups rather arbitrarily on the basis of age and diagnoses and twenty-nine control patients, selected to match the two major operative groups. Two operations were employed this time, one involving the excision of the upper quadrants of the frontal areas (superior topectomy) and the other, the excision of the lower quadrants, an orbital procedure. The conclusions of these associates are very similar to those of the "Rocklands" group and contain some interesting observations about all three studies—

(a) Psychosurgery, if effective at all, is of minimal use with deteriorated patients and of maximum use with psychoneurotic patients and pseudoneurotic schizophrenics.

(b) The excision of any particular area results in no more improvement than in any other—either the larger number of fibres severed when the lesion is in area "9," "10" or "46" or the higher percentage of patients having good prognostic ratings in the first report, could account for the apparent greater success after the excision of these areas.

(c) Little adverse personality changes were noted—the major change appeared to be the reduction of excessive affect with no change in mental content.

(d) The comparative value of topectomy and standard lobotomy has not been decided, but no operation should be attempted until all other indicated treatments have been tried.

Before leaving this series one should point out that despite their shortcomings, they are probably the most valuable collection of papers on the topic that has so far appeared. Particularly in the latter two reports there is evidence of an acute awareness of the need for more objective methods and excellent methodological discussions by Mettler, Landis, Zubin and Hoch are included in both. The chapter on "Psychiatric Effects" by Hoch *et al.*, in the New York State report, goes a long way towards rendering a psychiatric report objective, as objective as the method of subjective ratings will allow, and they present a plan for a properly controlled study of psychosurgery which would, once and for all, establish the connexion between operation and improvement rate, a connexion which remains, at the moment, tenuous.

The two reports from the Boston Psychopathic Hospital possess at once virtues lacking in the Columbia Greystone and New York Associates reports and lack virtues possessed by them. Large numbers of patients were seen (five hundred in the first report, Greenblatt *et al.*, 1950; one hundred and sixteen in the second, Greenblatt and Solomon, 1953) and relatively restricted and standardized operations were adhered to, but little awareness of the methodological problems of control and measurement, evident

in the latter two reports of the Columbia group, is apparent.

The approach of the two Boston Psychopathic Hospital reports, like those of the former three, is that of the "blunderbuss," the juxtaposition of the efforts of large numbers of contributors being once again considered beneficial. Lyerly-Poppen type operations were applied to all patients of the first group in this series and the general clinical conclusion was drawn that 25 per cent of the operated cases could be discharged and that the symptoms most affected were: tension, agitation, excitement and aggression and the disturbing qualities of obsessional ideas and of hallucinations. The subjects were primarily schizophrenic and the improvement figure of 25 per cent is very similar to the one given by Hoch *et al.* for the New York State group, which figure the latter regarded as very low and probably due to factors other than the operations. In view of the lack of controls in this report from the Boston Psychopathic Hospital, we also incline to the belief that chance factors could account for such an improvement rate.

The second of the two reports from the Boston Psychopathic Hospital has serious omissions in point of controls similar to the first. It was also largely concerned with a schizophrenic population and was designed to compare the effects of bimedial lobotomy with a unilateral procedure and a full standard lobotomy. The "control" technique employed was to allocate subjects at random to the three procedures, thus trusting that any differences found between the operative groups would be due to the operations. Provided that the allocation was really random and that the post-operative treatment was the same for all groups, this does not seem an unreasonable device. An improvement would have been to employ a control group to account for factors of spontaneous recovery and the effect of the "total push" to which the patients were subjected following their operations.

The general conclusions of this second study are—

(a) neither bimedial nor unilateral lobotomy is as effective as full standard lobotomy;

(b) the patient loses drive, energy and force;

(c) the patient is less affected by past experience and more bound to immediate stimuli;

(d) the patient is less able to elaborate experiences and less able to sustain them.¹

The investigations of both sets of "Associates," while clearly possessing certain serious weaknesses, represent advances on most of the purely psychiatric

¹ Paul *et al.* (1957) reporting on the long term follow-up of these patients claim that the bimedial procedure was superior. They quote improvement rates of 63 per cent for the bimedial operation, 44 per cent for the unilateral procedure and 31 per cent for standard lobotomy but do not statistically test for the significance of these figures.

investigations of the type illustrated in Table XV.1; they do present certain refinements in methodology.

One such refinement that should be mentioned briefly is that of the use of rating scales, either to assess behavioural changes directly or to develop a prognosis scale. Since we regard these techniques as essentially subjective, we include them here. Shrader and Robinson (1945) employed the Gardner Behaviour Chart (Wilcox, 1942) in the rating of sixteen schizophrenic patients before and after leucotomy (standard lobotomy) on fifteen scales. They concluded that the greatest change occurred in the appearance of patients and in their sociability. They also reported that the estimate of post-operative clinical improvement correlated (0.54) with pre-operative ratings and that the mean pre-operative rating of the fifteen scales was less favourable than the mean post-operative rating suggesting that the operations had produced an overall beneficial effect. The combination of ratings from different scales in this fashion could be a highly dubious procedure but, as they stand, Shrader and Robinson's findings agree with the observation made by the "Rocklands" group that the patient who is less seriously ill tends to improve. Bockoven and Hyde (1951) repeated Shrader and Robinson's earlier observation that sociability of patients was improved after psychosurgery. They applied a behaviour sampling technique to ten patients from the first Boston Psychopathic Hospital investigation before and after topectomy. They concluded that: "improvement consists of an increase of socialization accompanied by the development of a friendly, democratic attitude to other patients."

The studies of Sands and Malamud (1948) and of Becker and McFarland (1955) are primarily concerned with the development of prognostic scales as such, rather than with presenting information about the effects of psychosurgery. Sands and Malamud estimated the premorbid personalities of twelve schizophrenics and made ratings twice before operation and three times after operation. Their ratings were contrary to both independent estimates of improvement and the post-operative adaptation of the patient.

Becker and McFarland developed a twenty-three item rating scale battery from the records of the Columbia Greystone (Mettler, 1949) study, then applied it to the pre-operative records of three other groups of patients who had been subjected to psychosurgery. These authors then argued that, if their scales had been applied to these subjects before their operations, a considerable saving in operations and a proportionate increase in the percentage of improvements would have ensued. Unhappily no predictive as distinct from post-dictive validations are reported for their scales.

Freeman (1953b) derived ratings on the nineteen scales of the Malamud Rating Scale for 1,120 patients, of whom, six hundred and twenty-two had been subjected to standard procedures and four hundred and ninety-eight to transorbital lobotomy. Pre-operative ratings were made on the basis of case records and the relationship of these ratings to work and social adjustment, two years after operation, was examined. Freeman reported that the most favourable indications for psychosurgery were the presence of anxiety, obsessive thinking and self-directed violence as the principal symptoms complained of. Unfavourable indications were the presence of hallucinations, delusions, scattered thought disorders and externally directed violence. Despite the extreme subjectivity of this study, it would have been of considerable value, by virtue of the size of the sample alone if for no other reason, had some indication of the significance of the relationships been published. Unfortunately only frequency histograms have been given and mention made of chi-squares having been computed.

Another method of prognosis has been attempted by Kline and Tenney (1951) and by Kline *et al.* (1954) in terms of body types. The latter reported that of eighty-four patients, subjected to transorbital lobotomy, mesomorphic males and females with higher than average ratings in endomorphy showed the best prognosis in a three-year follow-up study. (Cf. Chapter 9 of this HANDBOOK by Linford Rees for a full consideration of the prognostic value of types of physique.)

Jackson and Jaco (1954) attempted to determine prognostic indicators for a group of five hundred and thirty-eight patients subjected to transorbital lobotomy. They reported that after remissions and unexpected recoveries, 52 per cent of the total improved group (57 per cent of all patients) were out of hospital while 96 per cent of the total unimproved group (47 per cent of all patients) were still in hospital. Chi-squares were computed between the improved and the unimproved group for a number of factors. They reported that sex (women), colour (negroes), involutional cases, paranoia, mixed schizophrenic diagnosis, a short duration of illness and of hospitalization, less than ten E.C.T.s, the absence of insulin therapy, being married, a higher education and a history of remission were all positive prognostic indicators and yielded significant chi-squares. Age, onset of illness, the presence of suicidal tendencies, birth order and the number of siblings yielded insignificant chi-squares and were judged to be unrelated to the likelihood of improvement after psychosurgery. Obviously many of the prognostic indicators these authors offer are intercorrelated, but their work contains important factual material.

Finally, we would like to refer to the more elaborate

investigations of Lorr *et al.* (1954, 1955) who employed factor analysis of ratings to identify the nature of the changes after psychosurgery in a group of schizophrenics. They made ratings on a number of "factors" of schizophrenia on a control group and an experimental group before and after the latter underwent psychosurgery. Two arrays of "change" scores were derived from the two sets of ratings—one for the control group, one for the experimental group. These two arrays were then factor-analysed to determine whether a single factor or several were required to characterize the change after operation. Their findings were that a single-factor of "improvement," more prominent in the operated group, was present together with a number of second order factors which, in an earlier study (Lorr, 1953) it had been shown, could be derived from their scales. Their conclusion was that psychosurgery accelerates a natural process of change. Clearly more elaborate procedures have their pitfalls as do those simpler ones with which we have heretofore been concerned.

In the first place, if we allow that the matrices of correlations, which appear to contain many significant coefficients, have not resulted purely from halo effects of the ratings, we are left wondering how change scores, from such unreliable measures as ratings, could produce anything other than completely insignificant matrices. In the second place, the inter-correlation of change scores as such is inappropriate on a number of grounds. It lacks generality of application in that, in the extreme cases of either no change at all or equal changes for each individual occurring, the correlation coefficients would be indeterminate and the analysis impossible. The fact that some significant correlations were found, merely suggests that some variation amongst the two groups of patients had occurred from test to retest and that the previous second-order analysis of the eleven factors of schizophrenia, held good. Nothing can be said about the direction of the change since concomitance towards worsening and towards improvement would contribute equally to the coefficients. The authors' identification of their first centroid as one of improvement, is thus completely unjustifiable.

Lastly, what interpretation one is going to put on the other three centroids, derived from the "change" score matrices, is quite obscure. Are they factors of change as such, as the authors suggest, or do they merely reflect the concomitance present in the earlier study (Lorr *et al.*, 1954)? What else would one expect to get out of matrices of change scores that was not in the basic scores? Certainly, if we allow that certain tests have been shown to change together, there is no possible way of showing that the togetherness was greater for the operated group than for the control group.

It is remarkable that the perfectly adequate table of pre- and post-operative scores (Table XV.3 of Lorr *et al.*, 1955) was not utilized in the discussion. Proper treatment of this table would have revealed all that the writers wanted to know, whereas the method they adopted, by its very nature, leaves these mean change scores out of account. As the table stands, it is interesting to note that mere inspection would suggest that both groups show slightly higher ratings post-operatively, the control group as much as the operated group.

Such studies as these, employing rating scales yield then very inconsistent information. As mentioned earlier, pen-portraits of the post-psychosurgery patient are a highlight of many clinical papers and, in fact, they do seem to perform the function of presenting the nature of the raw data at least vividly. To suggest then the nature of the raw data presented by post-psychosurgery patients, we would like to quote the pen picture given by Frankl and Mayer-Gross (1947) derived from their observations of sixty-eight leucotomized psychiatric patients—

The patient is physically healthy, a good eater and sleeper with considerable euphoria. His prevailing mood is cheerfulness; he does not worry, is happy and contented and shows it. He may take his responsibilities too easily or shirk them altogether. He leads an active life, is restless and likes movement and change. His interests and hobbies are varied and variable with a preference for light entertainments and superficial pastimes. He is easy-going, a good mixer and fond of social life and of being on good terms with everybody.

On the other hand his relations with people around him are often without depth of feeling. He shows little sympathy or consideration for his next of kin or anybody else. He may be head-strong and unable to see the other person's point of view. He tends to quickly passing bursts of temper. He may attend to his work as before or he may do less well but invariably he thinks he does well, he is not a perfectionist.

Animal Studies Related to Clinical Investigations

Before concluding this section we would like to review briefly a number of investigations with animals, bearing directly upon the questions of the efficacy of psychosurgery and the nature of the changes wrought by it. The methods employed in many of these studies bear close resemblance to the subjective methods of the clinical studies we have been discussing, since the animals' behaviour has been frequently rated by the experimenters rather than measured objectively. For this reason we are including these studies here, rather than in that later section where investigations that have employed objective measures throughout are described.

It should be noted that the data being reported here have often been presented with observations on

cognitive changes that have usually involved objective measures. These observations have been included, partly for convenience and partly because these cognitive changes appear to bear directly upon the orectic alterations, in a manner to be elucidated.

Masserman, for a long time, has been concerned with the investigation of the aetiological factors in neuroses through comparative studies and, in collaboration with others, has presented three papers which are of relevance here.

Pechtel *et al.* (1955) reported on the behaviour of seventeen cats which had been observed before and after they had been subjected to a stereotactic procedure similar to that of Spiegel and Wycis *et al.* (1948), an experimental neuroses having been established pre-operatively. These writers were partly interested in the effect of thalamic lesions on olfaction, which does not concern us here; their findings, germane to the matters we are discussing included—

(a) after stereotactic destruction of the mediodorsal nucleus, extensive amnesias for previous learning occurred in all animals;

(b) amelioration of acquired neurotic behaviour was noted;

(c) diminution in the speed and capacity for new learning was observed; motivation was retained at a pre-operative level but the animals were perseverative and stimulus-bound;

(d) intensified affective behaviour in relation to other animals and towards humans was observed;

(e) a change in characteristic social responses was seen, dependent upon the pre-operative experiences of the animals, i.e. cats who were made experimentally neurotic were significantly more aggressive after mediodorsal thalamotomy than were a group of normal controls after the same operative procedure.

Masserman and Pechtel (1956a) rated the behaviour of fifty cats and forty monkeys on thirty behaviour categories over periods of five months and measured their capacity to perform certain learning tasks. Approximately half the animals were then subjected to a procedure which induced experimental neuroses. The neurotic behaviour so established was allowed to stabilize over periods of between three and twenty-four months. The animals were then subjected to frontal excisions and their behaviour rated again. These writers record that the common effects of the lesions were—

(a) moderate or excessive amnesia;

(b) amelioration or disorganization of the neurotic patterns of behaviour;

(c) diminished adaptability in behaviour leading

to (i) stimulus-bound perseveration, and (ii) impaired skill in problem-solving;

(d) affective changes, characterized by greater susceptibility to reactions indicative of startle and fear.

This second study, it can be seen, largely corroborates the findings of the first. Masserman and Pechtel (1956b) present some further corroborative evidence for these findings in a study which suggests that monkeys with brain lesions are slightly less resistant to and recover slightly less rapidly from procedures aimed at establishing experimental neuroses.

Each of these experiments is interesting but in respect of the light they shed on the changes wrought by psychosurgery their findings are equivocal. In both the first and second study quoted, some reduction of the neurotic behaviour patterns was reported but what patterns were labelled neurotic seemed rather arbitrary and any change in them would appear much more likely to be associated with some of the more general changes observed—the amnesias for instance, or the reported tendency towards being stimulus-bound. Indeed, on the contrary, some of the changes that were noted appeared to be of the type which, in human subjects would have been regarded as signs of increased neuroticism—for example, “increased affective behaviour,” “greater susceptibility to reactions indicative of startle and fear.”

Streb and Smith (1955) have reported findings similar to these, using rats as subjects. Fifty rats were trained to give a “crouching fear” response to the sound of a buzzer. Half of these animals were then subjected to partial ablations, the other half underwent sham operations. After recovery from the operations both groups were tested again and it was found that a significantly higher percentage of experimental animals who had suffered ablations, had lost the crouching response. The results suggest that, analogously, psychosurgery might well reduce anxiety in human subjects. Streb and Smith point out, however, that the same differentiation between the experimental and control group would have been achieved had mobility about the cage been the criterion and that, what measured reduction in “anxiety” did occur, occurred as part of a more general alteration of response tendencies.

Lichtenstein in two well controlled studies (1950a and 1950b) first outlined a method for inducing a “feeding inhibition” in dogs and, as in the succeeding studies reported above, utilized this neurosis in testing the efficacy of a psychosurgery-type procedure in dispelling such maladaptive responses. Through the controls he employed, Lichtenstein hoped to show that his results were not artefacts of the lapse of time occupied by the operation and the recovery from it,

of the circumstances attendant upon the operative procedures—the anaesthetic for example—and that the results did not differ when different periods of time were allowed to elapse after operation. He reported, tentatively, that the experimental groups lost their feeding inhibitions to varying extents, depending on the animal.

Lichtenstein's final conclusions were, however, cautious. He pointed out that since the operations had resulted in widespread biological changes, the disturbance of established responses could have as readily been due to these changes as to the presence of lesions as such. If we couple this reservation with the smallness of his groups (four dogs in each of two experimental groups) and the fact that after the original operation one dog retained the feeding inhibition unimpaired and others retained it to a greater or lesser degree, we must conclude that Lichtenstein's results are completely equivocal. Lichtenstein reported one further interesting finding in that he suggested that after the frontal lesions the feeding inhibition could be established slightly less readily than before them. This finding is also tenuous in that it was based on the observation of only two animals.

Waterhouse (1957) stressed this element of retraining in a similar investigation employing monkeys. Eight animals were trained to make a five-second delayed response, a pattern discrimination and a colour discrimination. He further established a fear response to two kinds of auditory stimuli and avoidance responses to food. Four of the monkeys were then subjected to an operative procedure which severed some of the fibres in all of the corticothalamic tracts in the frontal lobes. Waterhouse reported that his post-operative monkeys showed a marked loss in the retention of their previously learned responses, although a fairly high level of performance was still evident. Relearning was possible nearly to the same level as was achieved pre-operatively.

Of direct interest to our concern in this section are the qualitative changes Waterhouse noted in the responses of the post-operative monkeys. He reported that they were both slower and less "forceful" in their responses. Again, also, a rapid extinction of learned responses was observed. Concerning the specific responses of conditioned fear and food avoidance, both these were reduced post-operatively and, although there was no significant difference in the extent to which these reductions occurred, the indication was that the fear response was more completely lost.

Considering these investigations together, their most clearly delineated feature is the probability that neurotic responses diminished as a function of some more general change. The present writer would like to suggest that the identity of this general change is a deficit in the formation and retention of conditioned

responses. Waterhouse suggests very much the same conclusion and, with it in mind, draws the following implications from his investigation for psychiatric thinking around the problem of the effects of psychosurgery—

the following need close attention; (a) the extent to which lobotomy in humans leads to the extinction of fear and symptoms motivated by fear; (b) how far fear-based symptoms may be re-learned again if re-inforced in an unfavourable post-operative environment; it would also suggest careful study of any impairment of the alerting process in anticipation of danger and in the processes that sustain affective arousal; (c) finally, it poses the interesting more general problem of whether lobotomy leads to any deficit in the learning and retention of responses based on acquired motivation.

In addition to these reports bearing directly on the question of the efficacy of psychosurgery, there have been a number of comparative studies that have made more or less unsystematic observations of "emotional" behaviour following frontal ablations in animals. Such observations have not always been made with a view to drawing parallels with post-psychosurgical behaviour in human subjects but they have some relevance to this problem and to the original observations of Fulton and Jacobsen.

Harlow and Dagnon (1943) noted that their group of monkeys showed resistance to taming and habituation procedures and attempted to bite the experimenters after frontal lesions. There seems some parallel here with the frequently reported lack of emotional restraint after psychosurgical procedures and, possibly, also the behaviour is related to the suggested impairment of the acquisition and retention of fear-based responses previously noted.

The observation of Harlow and Dagnon was repeated by Harlow and Settlage (1947) and by Harlow *et al.* (1952). The latter conclude that—

in no observation of animals with anterior lesions has this laboratory been able to confirm the reports of emotional flattening and indifference to failure that were instrumental in the initiation of the technique of pre-frontal lobotomy. Instead the behaviour changes have been in the opposite direction.

It is possible that the cause of these discrepant reports might lie in the finding of Freudenburg *et al.* (1950). These writers repeated the observations of Fulton and Jacobsen (1935) on Rhesus monkeys, comparing the effects of lesions in the frontal areas with lesions in the dorsomedial nucleus. They reported that complete "taming" occurred when the lesions were placed in the coronal plane and were accompanied by degeneration of the dorsomedial nucleus; taming also occurred when the lesion was

placed directly in this body. In the absence of the dorsomedial body being involved no taming was observed. It will be remembered that the lesions introduced by Fulton and Jacobsen were massive and almost certainly would have involved this body. If the lesions introduced by Harlow and his associates were more restricted the dorsomedial nucleus might not have been involved and, in agreement with the report of Freundenburg *et al.*, taming not have occurred.

A second commonly reported effect of frontal ablations in comparative studies which has some relevance to our purposes is the observation of hyperactivity. Richter and Hines (1938) give an excellent review of the early work in this field, including the most important studies carried out before 1938, during which period the phenomenon received a great deal of attention. A selection of studies since that date will serve to illustrate the nature of these data.

Richter and Hines had concluded from their review that both unilateral and bilateral removal of frontal lobes resulted in hyperactivity, the effect being heightened if the bilateral procedure followed the unilateral operation. They further concluded that areas "8," "9," "10," "11," "12" and the anterior ends of the caudate nucleus were the crucial areas involved. Kennard *et al.* (1941) largely confirmed these conclusions although they did not place so much stress upon area "9" or upon sections of the striatum. These latter workers utilized good control conditions and were thereby able to demonstrate that changes in metabolism and other autonomic disturbances were not causing the hyperactivity.

Wade (1952) compared the behaviour of monkeys following a leucotomy procedure with a lobectomy and an operation which severed some of the trans-sectional fibres. She reported a consistent pattern of increased activity after both of the former two operations but none after the third. Her results would suggest, like those of Freundenburg *et al.*, that the mere presence of a lesion as such would not produce any dysfunction and that rather it was the severing of frontal association fibres at any of several sites that would effect the change.

One further general observation, of some relevance to this section and in line with studies already quoted, was made by Brody and Rosvold (1952). These writers investigated the effect of frontal lesions on social interaction amongst a group of *macacaemulatae*. Within this group, comprising six monkeys, a dominance hierarchy was allowed to build up and become stabilized over a period of three months. Half of the monkeys were then subjected to frontal ablations and observations of the dominance hierarchy was continued for another seven months. The authors report that

the hierarchy was disturbed after the operation and was never re-established. They suggest that the breakdown occurred because of the lower-status monkeys' failures to retain or relearn their previously strong avoidance responses after the frontal excisions. This finding also is in line with our previous suggestion as to the nature of the orectic changes that occur after frontal lesions in animals.

The general conclusions that can be drawn from these comparative studies are thus clear. While amelioration of specific "neurotic" responses is suggested, the application of this finding to the matter of the efficacy of psychosurgery is rendered difficult by the concomitantly reported findings after ablations in animals of behaviour changes reminiscent of the disturbed affect of psychiatric patients. This apart, the reported reduction in experimental neuroses appears to be part of a more general deficit—one of decreased capacity to form conditioned fear responses.

General Conclusions Concerning Clinical Studies

From a consideration of the literature, the above description of sections of it and the data presented in Table XV.1, we would draw the following conclusions concerning the clinical studies of the effects of psychosurgery on behaviour—

(a) the therapeutic benefit of psychosurgical procedures remains essentially undetermined by clinical studies and the related comparative work, although many studies contain observations suggestive of certain changes;

(b) the changes that are suggested towards clinical improvement are much more evident for the non-deteriorated, largely non-psychotic patient;

(c) the nature of these putative changes appears to be a reduction in the intensity of affect; more particularly, in a reduction of the intensity of anxiety and tension states (conditioned fear responses in experimental animals), of compulsive-obsessional symptoms and reactive depressions, the disturbing quality of acute physical illnesses and of hallucinatory and delusional experiences;

(d) the superior benefits of any one procedure are also undetermined by these studies, although the negative *sequelae* of standard lobotomy, do seem to be rather more severe than those of more restricted operations.

Arising from these conclusions and the review of the clinical data upon which they are based, we wish, now, formally, to suggest an hypothesis as to the mode and type of change wrought by psychosurgical procedures, which hypothesis we shall examine whenever relevant data appear during the course of our subsequent general discussion.

enck has described the structure of personality in terms of a number of factorially determined dimensions (1947, 1952, 1957*a*). These dimensions (*see* Chapter 1 of this HANDBOOK) are, neuroticism, introversion-extraversion and psychoticism. Neurological parameters have been suggested for the former two dimensions, which parameters should be regarded as hypothetical constructs. That parameter postulated as underlying neuroticism is a quality of lability in the autonomic nervous system and is often, in Eysenck's writing, regarded as manifest in anxiety and thought of as a drive state. That underlying introversion-extraversion has been postulated as a state of balance of the excitatory and inhibitory potentials of the central nervous system. In Eysenck's system the neurotic is characterized by an overly labile nervous system. The introvert is characterized by a predominance of *excitatory* potential while the extravert is thought of as being characterized by a predominance of *inhibitory* potential. Thus, when applied to psychiatric patients, this theory envisages the tense, anxious, compulsive, obsessive, phobic patient as possessing high degrees of both neuroticism and introversion. Conversely the hospitalized psychopath and the patient suffering from any of a variety of hysterical symptoms is seen as possessing high degrees of neuroticism and extraversion. Psychoticism refers to states where autisms and cognitive disturbances are pronounced—in those patients frequently labelled schizophrenic, for example.

Introversion-extraversion has been related to learning constructs (Eysenck, 1955*a*, 1955*b*, 1957*a*) and, in particular, Franks (1956) showed that a group of extraverts formed conditioned eyeblinks less readily than a group of introverts, when neuroticism was held constant (*cf.* Chapter 12 of this HANDBOOK).

Bearing this in mind, and the nature of the proposed dimensions, we would suggest the following hypothesis for the nature of the changes following psychosurgical procedures—

Those who advocate psychosurgical procedures seem, from their writing, to be striving to effect changes in the degree of neuroticism and psychoticism. The evidence reviewed above suggests that psychosurgical procedures result in a reduction of introversion.

The evidence for this hypothesis so far presented may be summarized briefly as follows: in those illnesses where the role of introversion is maximal—in anxiety states, in the presence of inappropriately learned responses (in phobias for example) or in states of tension—the benefit of psychosurgery seems to be maximal (Freeman, 1942, 1949; Hutton, 1947; Frankl and Mayer-Gross, 1947; Van Wagenen, 1946; Arnot, 1949; Cattell, 1950, 1953; Reiner and Sands,

1951; Allison and Allison, 1952, 1954; Kalinowski and Hoch, 1952; Freeman, 1953*b*; Greenblatt and Solomon, 1953; Hurt, 1947; Miller, 1954; Pippard, 1955*a*). Where extraversion is present to a high degree, in psychopathy for example, the benefits of psychosurgery are generally held to be minimal (Cattell, 1953; Kolb, 1953; Ackerly in Overholser, 1954). Likewise, where the disease process appears to involve fundamental structural or biochemical changes, as in the presence of psychoses, more particularly in the presence of psychotic deterioration, the operation also appears to be of little value (Johnson and Ehrenberg, 1951; Rothschild and Kaye, 1948; Mettler, 1952; Kalinowski and Hoch, 1952; Freeman, 1953*b*; Shevenko, 1954).

Finally, the comparative work so far reviewed—as has been intimated—strongly suggests that conditioned fear responses in experimental animals is reduced and this finding is congruent with that of Franks (1956) on human extraverts.

The status of the proposed hypothetical construct underlying introversion-extraversion is quite clear in the case of Franks's study—that extraverts should condition poorly follows directly from the proposal. That an increase in the relative dominance of the inhibitory potential should follow circumscribed lesions in the frontal cortex does not follow so obviously, although it would be possible to develop a plausible account in very general terms. The writer, however, feels that the very considerable advances that are being made in neurophysiology at the present time (Delafresnaye, 1954; Sprague and Chambers, 1955; Stellar, 1957) would immediately reveal the weaknesses of any such general account and it would seem best to tie any hypothesis about the action of psychosurgery closely to behaviour.

That extraverts condition more poorly than introverts is consistent with the hypothesis about extraversion and the predominance of cortical inhibition and, if it were shown empirically that post-leucotomy patients conditioned (to mention but one prediction) less readily than pre-leucotomy patients, this would be consistent with the proposal that the operation results in an increase of extraversion. It would also be consistent with the notion that an increase in the predominance of the inhibitory potential follows frontal lesions. These and other related findings might well form a nomological network of hypotheses having considerable explanatory power at the behavioural level. No direct prediction, however, carrying any high degree of conviction can be made, at the moment, from the introduction of frontal lesions into the cortex in terms of the neurological constructs Eysenck has proposed as underlying introversion-extraversion.

A full-scale investigation constructing such a nomological network by relating postulates involving the

concept of inhibition (in, for example, learning and perception) and independent measures of introversion-extraversion to the effects of psychosurgical lesions is suggested by these notions. Such an investigation has not been carried out, hence most of the evidence we

shall present in support of our hypothesis refer to the behavioural pattern Eysenck has labelled introversion and extraversion. Little or none of this evidence directly involves the postulated underlying neurological construct.

STUDIES IN PERSONALITY CHANGES AFTER PSYCHOSURGERY

In turning, as we shall now do, to the assessment of personality changes after psychosurgery we must stress that the tools of measurement, commonly known or available to psychologists who have worked in this field, are most limited and of uncertain value. It is not surprising, then, that the general level of investigation in this area is rather lower than in the investigations of intellectual changes which we shall report in the next section.

Those studies we shall be concerned with here are of three main types: (a) investigations using the Rorschach Inkblot test or other projective devices; (b) investigations employing questionnaires and (c) investigations in which the use is made of batteries of performance tests thought to describe unitary factors of personality.

Projective Techniques: the Rorschach Test

The Rorschach Inkblot Test (Klopfer and Kelly, 1942, 1946) has found favour with many medical people and many clinical psychologists. It has been accredited with the twin virtues of being a "test" and thus seemingly objective, while in interpretation it is said to require those puissant faculties of clinical insight and intuition so dear to many clinicians. In spite of these qualities the validity of the Rorschach as a diagnostic tool has often been questioned (e.g. Payne, 1955) and in the absence of any final answer to this question, we cannot give too much credence to personality assessments based on it. It has, however, been employed very often with psychosurgical patients and we will make a report of some of the typical studies.

First, we shall summarize briefly the findings with the Rorschach from the large-scale studies referred to in the previous section. In the first report of the Columbia Greystone Associates, Zubin found no definite pattern of changes in scores following the operation, and what changes were suggested were equally prevalent amongst members of the control group. A statistical analysis of individual records revealed no significant differences between the control subjects and those who had undergone the operations. The only significant change was in the speed of reaction-time to the cards; the post-operative group was the slower.

No reference was made to the Rorschach Test in either of the later two reports connected with these

workers, the "Rocklands" study (Mettler, 1952) or the report of the New York Associates in Brain Research (Lewis *et al.*, 1956).

Hunt, in the first edition of *Psychosurgery* (Freeman and Watts, 1942) reported that the post-leucotomy patient showed a constriction of personality, some loss of "higher powers" and exhibited a greater preponderance of "popular" responses in their Rorschach responses. The earlier of the two reports from the Boston Psychopathic Hospital (Greenblatt *et al.*, 1950) reached very similar conclusions from its application of this test. The authors in summarizing their findings with the Rorschach write—

Rorschach studies before and after lobotomy indicate slight but consistent impairments in abstraction capacity plus a great deal of indecision. The patients show more perseveration, more stereotypy, less fantasy and creative imaginativeness and reduced spontaneity and initiative. Freer emotional expression and fewer restrictions in the patients' affect were noted within the narrowed emotional range. These changes frequently interfered with judgement.

Greenblatt and Solomon (1953) found little reason to change this summary materially but added some observations concerning indications of anxiety. They reported for this second group of patients (some twenty-eight, tested between four and eight months after operation) that ratings of anxiety, derived from Rorschach protocols, remained the same as they were before operation and that the protocols after operation were still, characteristically, psychotic in kind. No further changes were noted on retest after twelve months, other than a reversion in some patients to a pre-operative level of emotional control and a marked increase in the amount of fantasy evident in the protocols of two patients. It was also concluded by these authors that the Rorschach protocols "had little if any relationship to clinical outcome."

Numerous other studies have employed the Rorschach Test to investigate the effects of psychosurgery on behaviour. Kisker (1944b) tested a group of severely psychotic patients before and after leucotomy on this test. He made only a "qualitative" judgement of his protocols because of the greatly disturbed character of his subjects. One can only suppose, that by "qualitative" judgement here was meant that the protocols were not scored according to one of the

accepted systems (Klopfer and Kelly, 1942, 1946). The outcome of this rather unpromising beginning was rather along the lines of the other studies so far reported. Only very small changes were noted and it was claimed that their character was often anticipated in the pre-operative records.

Spiegel and Wycis (1949) were unable to demonstrate any consistent pattern of change in Rorschach responses in nine cases subjected to their stereotactic procedure although (a little forlornly one feels) they suggested that five of their nine cases showed some "improvement on the Rorschach criteria."

Crown (1952) in a well-controlled study of thirty-five, largely psychotic patients, reported a significant decrease in "F" scores, which decrease he suggested might be a reflection of the common clinical report of a "blunting" of tact and of a lessening of richness and originality in response.

Linford-Rees and Jones (1951) attempted to evaluate the effects of leucotomy and various other "active" therapies by means of the Rorschach Test. They reported that failures after leucotomy had significantly lower organic signs of Piotrowski although the test had little prognostic value. Their first mentioned finding is of some interest and accords well with the contention, found frequently in the literature, that too restricted a lesion is ineffective.

McFie, Piercy and Zangwill (1951) investigated a group of obsessional patients who had been subjected to psychosurgery and were likewise unable to demonstrate any change following the operation, or any consistent pattern of "obsessionality" for that matter, in the Rorschach protocols. They were able to report, however, that the obsessional patients tended towards "blocking" and exactitude in their pre-operative responses and that these tendencies disappeared from the immediate post-operative protocols although they became evident again in later testing periods. If any reliance at all can be placed on these latter observations they would suggest the somewhat tardy re-learning of disturbed patterns of response after psychosurgery which was suggested as a possibility by some of the previously reported animal studies.

Davidson (1952) obtained scorable Rorschach protocols on twenty-eight patients suffering from schizoid and "affective" disorders before and after they were subjected to leucotomies. He reported, once again, a poor correlation between Rorschach responses and clinical findings.

Wideman (in Miller, 1954) administered the Rorschach Test to sixty-one patients, after leucotomies, and reported that anatomical responses discriminated between an improved group and a non-improved group, such that 43 per cent of the former gave them and 73 per cent of the latter. This, however, was the only one of a number of Rorschach scores which did

show any discriminatory power and could easily have been a chance finding.

Reitman (1955*b*) administered the Rorschach Test to a group of mixed brain-damaged patients, including some post-leucotomy patients. He compared the protocols of this group with those of a group of non-brain-damaged psychiatric and paraplegic patients. Contrary to the studies so far reported he found that all scores of the brain-damaged group other than w and F were significantly different from the scores of the psychiatric and paraplegic patients. He interpreted this difference as indicating that the brain-damaged group was characterized "by a general suppression of personality factors." This latter presumably means something the same as the "constriction" of personality reported by Hunt, although one cannot be at all sure of the implications of this description either.

Finally, we wish to report what is probably the best controlled study of its type in the field. Allison and Allison (1954) compared the pre-operative and post-operative Rorschach protocols of eight subjects undergoing transorbital lobotomy. Pre-operatively each subject was matched with a control on: diagnosis and treatment, period of hospitalization and duration of illness together with age and sex. One month prior to operation all subjects were given a Rorschach Test and henceforth lived together under the same closely supervised conditions up to the time of the operation. All subjects received the same pre-operative work-up and preparation, including the administration of a number of electroconvulsive shocks which served as the anaesthetic for the experimental group's psychosurgical procedure. All subjects received the same post-operative care and, after being tested post-operatively, their two sets of records were marked in random order and scored "blind."

The obtained sets of scores were then subjected to statistical analysis. Statistically significant decreases were found in m and FK scores and in the speed of responding to the cards (confirming Zubin's finding mentioned previously). A significant increase was found in w scores. Decreases in k, K and M scores and an increase in the frequency of the organic signs described by Dörken and Kral (1952) all approached significance. A non-parametric test of significance applied to the scores arranged according to the check lists of Harrower-Erickson (1942) and of Munroe (1945) also showed significant changes. These authors conclude, on the basis of these results, that the characteristic changes in their patients were—

(a) reduced tension and anxiety (lower m, k and K scores)

(b) loss of the ability to introspect (lower M scores)

- (c) loss of enthusiasm (slower reaction-time)
- (d) improved organizational ability (increased w)
- (e) reduced creative ability (lower M).

They summarize their findings by claiming that their results corroborate many of the impressions that have been made clinically.

Despite the excellence of their design and execution of the work, one can, however, accept their findings only with reservations; particularly their interpretation of the change scores which is the only part of their study, albeit a crucial part, that is in any way subjective. To take only one patent example, one can see no compelling reason why slower reaction-time should be identified as loss of enthusiasm. One cannot but lament that such an excellently planned and executed piece of work should have utilized such a poor and suspect measure of personality as the Rorschach.

It will be noticed that one of the results of the above studies was interpreted as loss of creative ability. Many such references are to be found throughout the literature and should be mentioned here.

Hutton and Bassett (1948) used a number of techniques to demonstrate this putative deficit, including the orthodox Rorschach Test, the multiple-choice version of Harrower-Erickson (1942) and Murray's Thematic Apperception Test. They suggested that while the level of general intelligence remained high post-operatively (as measured by the Raven's Matrices and the Shipley Hartford Scales) originality and creative ability were considerably reduced. They took as measures of these latter the originality and number of the patients' responses to the various projective tests administered. Ashby and Bassett (1949) and Crown (1952) reached very similar conclusions although Reitman (1947) had described a contrary creative "spell" in a schizophrenic patient subjected to a psychosurgical procedure.

Zubin (in Overholser, 1952) has virtually settled this issue. He reported a number of systematic attempts to validate the Rorschach Test (number of M responses) as a measure of creativity by comparing the number of M responses given by groups of artistically gifted people with the number given by matched controls equally intelligent but less creatively gifted. In none of these attempts did the Rorschach discriminate between the two groups.

Zubin went on to characterize creative ability as being composed of, imaginativeness, problem-solving ability, skill and zeal and made a number of observations upon patients and their behaviour to determine whether any sign of any of these constituents being deficient, after psychosurgery, could be discovered. His observations were quite subjective, but such as his conclusions were he could find no evidence of any deficit in any of these factors.

Conclusions From Projective Test Studies

In general then we must conclude from this brief review of the projective test studies into the effects of psychosurgery, that, in point of the most objective aspects of the tests, only the study of Allison and Allison (1954) has unequivocally demonstrated any changes post-operatively. We have pointed out that we can accept their interpretations of their results only with reservations due to the subjectivity of these interpretations.

Questionnaires

Far fewer studies have utilized the much more objective method of measuring personality—the questionnaire. Vidor (1951) administered the M.M.P.I. scales to a group of leucotomy patients pre-operatively and post-operatively. She reported that the scales of "depression" and "psychasthenia" showed significant decreases. She also reported a decrease in the number of items which seemed to reflect the presence of anxieties, phobias, depression and hallucinations.

Darling and Sandall (1952) in a curious paper, report the administration of the M.M.P.I. to a group of eighteen hospitalized psychopaths who had undergone leucotomy. They do not burden the reader with scores or other cumbersome details but are happy, nevertheless, to conclude that their results support their convictions that psychopathic illnesses are as serious as psychoses and are caused by environmental stresses on hereditary predispositions; a conclusion which shows a most prudent regard for the complexity of the subject.

Reitman (1955c), using the same group as he did in his study of the Rorschach, administered the M.M.P.I. scales. He reported that the greatest differences here were that the brain-damaged group had *higher* scores on the "paranoia," "psychasthenia" and "schizoid" scales. The implications for psychosurgery from Reitman's studies must be tenuous since he used a mixed group. In particular we cannot conclude from his study that psychosurgery results in *increased* psychotic tendencies for we are given no pre-operative scores, nor do we know how well Reitman's control group matched his brain-damaged group in point of severity of psychiatric symptoms.

Conclusions from Questionnaire Studies

The conclusions from these questionnaire studies are clearly equivocal; they have yielded surprisingly little information.

Factorial Studies Using Objective Performance Tests

The dimensional approach to the analysis of personality has been referred to at length in a preceding chapter by Eysenck (Chapter 1). He, together with Cattell and Guilford, based partly on the

pioneering work of Spearman, Thurstone and Burt, has been the principal proponent of this methodology which aims at reducing the multiplicity of response tendencies, that go to make up the totality we call personality, into a relatively small number of dimensions or factors. This is achieved by demonstrating broad bands of concomitances, amongst such response tendencies, through the technique of factor analysis or some related procedure. The principal studies that have utilized this approach in the field of psychosurgery are those of Crown (1952) and of Petrie (1952), both of whom have employed the framework provided by Eysenck (1947, 1952, 1957*a*).

Crown (1952) in the study already mentioned several times, predicted decreases in general intelligence, in neuroticism and in introversion. As measures of the latter two, he used batteries of performance tests by which Eysenck (1947, 1952) defined these factors. Crown's subjects were thirty-five psychotic patients of various diagnoses. He found that there was no consistent change post-operatively in either neuroticism or introversion. The absence of any marked decrease in neuroticism we would have expected; that no decrease in introversion occurred requires explanation since it apparently involves a direct contradiction of the hypothesis we have suggested for the nature of the change that takes place after psychosurgery.

In the first place, the tests Crown used, although the best available measures of the factor at the time, would not necessarily be those one would choose now if changes in introversion were being examined after leucotomy. More reliable measures would be derived from questionnaire scores (Eysenck, 1956) and various indices, taken from laboratory learning, perception and conditioning situations (Eysenck, 1957*a*), would be employed, rather than the earlier performance tests.

In the second place the subjects Crown used were psychotic, as has been described, and it seems probable that factors of attention, slowness, concentration, etc., frequently attendant upon psychotic disorders could have affected the performance test scores on which the measure of introversion-extraversion was based and if, as we suspect, psychotic elements remain unaffected by psychosurgical procedures, one would not expect any differences on test performances from the pre-operative occasion to the post-operative occasion.

This criticism of the choice of subjects for psychosurgery investigations has been made by Petrie (1952) and, more recently, by Tow (1955). Both accordingly drew their experimental samples from neurotic populations having well preserved personality structures.

Petrie chose to test groups who were predominantly suffering from functional disorders such as compulsive-

obsessional complaints, reactive depressions, anxiety states and, in general, those groups which Eysenck has termed dysthymic—those, in short, in whom we would predict the maximum change after psychosurgery.

In her original monograph (1952) Petrie presented the results of testing such groups of patients who were subjected to a standard lobotomy, a rostral procedure and a third smaller group who received only unilateral incisions. She has since published separately and with the collaboration of the French neurosurgeon Le Beau and his psychological associate, Maryse Choppy, a series of studies utilizing the same methodology on groups of patients subjected to various selective procedures (Le Beau and Petrie, 1953; Petrie and Le Beau, 1953; Petrie and Le Beau, 1956).

The subjects of the original monograph, which forms the basis of the work that followed, were tested approximately two weeks before operation and, in the case of standard lobotomy, at intervals of three and nine months after operation. In the case of the more anterior rostral operation, they were tested only once, six months after operation. In general, the same intervals have been adhered to in the investigations of the selective procedures, for purposes of continuity and comparison. Petrie summarized her findings from the first investigation as follows—

the pattern of personality changes has been shown to be consistent in the four different types of operations examined and the alterations in the traits may be readily grouped so as to demonstrate changes in the dimensions of personality, viz.: a decrease in the strengths of traits associated with neuroticism and with introversion and a decrease in certain aspects of intelligence . . . alterations in personality are more pronounced after the posterior standard operation than the anterior rostral operation, particularly . . . in the sphere of intelligence.

Petrie's method of investigation has been the same for all groups of subjects tested. Table XV.2 shows the results from the original monograph rendered comparable with those of some later studies into the effects of selective procedures and including one group seen before and during the administration of the pseudo-leucotomizing drug, chlorpromazine. It will be noticed that one further factor, psychoticism, has been added to those factors originally studied. Many of the tests defining this factor were administered to Petrie's original group of subjects and these were later arranged to show changes along this dimension.

For a full description of the tests Petrie employed, reference should be made to her monograph (1952) but scrutiny of Table XV.2, as it stands, reveals a number of points for consideration.

TABLE XV.2
SHOWING PERFORMANCE TEST SCORES ARRANGED UNDER THE
RELEVANT FACTORS OF PERSONALITY

(Adapted from Petrie and Le Beau, 1956)

	Chlorpromazine 19 pain and mental patients		Cingulectomy 15 epileptic patients		Standard leucotomy 20 neurotic patients		Open rostral leucotomy 15 neurotic patients		Selective surgery of areas "9" and "10" 19 pain and mental patients

* Significant differences ($p = 0.05$ or higher).

† d.o.p. = decreased orientation to present; i.o.p. = increased orientation to present; n.c. = no change; inc. = increased.

○ Mean difference scores derived by the subtraction of pre-operative scores from post-operative scores.

— Changes in the direction of decreased neuroticism, increased extraversion, and decreased psychoticism.

□ A relatively greater increase in performance I.Q. in comparison to verbal I.Q. taken as a change in the direction of increased extraversion.

First, it is clear that the most definite changes occurred with the original standard and rostral groups. In each of these groups the changes in the direction of decreased neuroticism are consistent and significantly different when compared pre-operatively and post-operatively. Also for these groups those tests related to introversion-extraversion change consistently in the direction of decreased introversion, half of the differences between pre-operative and post-operative scores being significant ones.

The position with respect to the selective procedures is not so clear. Consistent changes in both introversion-extraversion and neuroticism were recorded for the group subjected to selective surgery of areas "9" and "10" towards increased extraversion and decreased neuroticism and, as is in line with other reports in the literature, there was no consistent alteration in psychoticism. As can be seen, however, very few of the changes recorded reach statistical significance and some differences are extremely small.

TABLE XV.3
SHOWING PERFORMANCE TEST SCORES ARRANGED SO AS TO BE
COMPARABLE WITH TABLE XV.2

(Adapted from Tow, 1955)

Test		N	Post-op. mean	Pre-op. mean	Mean diff.	p value
<i>Tests probably related to neuroticism</i>						
1. Speed—						
(a) Letter cancellation (number cancelled)	(i)	36	142.0	143.0	—1.0	N.S.
	(ii)	36	135.0	137.0	—2.0	N.S.
(b) Track tracer (time for completion in sec)	(i)	36	98.0	103.0	—5.0	N.S.
	(ii)	36	87.0	98.0	—11.0	N.S.
(c) Porteus mazes (time in sec)	(i)	34	546.0	313.0	233.0	p = 0.01
2. Persistence—						
(a) Word formation (total number)	(i)	36	34.0	43.0	—9.0	N.S.
(b) Holding up leg (time in sec)	(i)	36	50.0	57.0	—7.0	p = 0.03
3. Troubles questionnaire—						
(a) Number of troubles ascribed to self	(i)	31	10.0	15.0	—5.0	N.S.
4. Disposition rigidity—						
(a) Easy alternations (ratio of first to second task)	(i)	36	2.3	2.4	—0.1	N.S.
	(ii)	36	2.8	2.9	—0.1	N.S.
(b) Difficult alternations (ratio as in (i))	(i)	36	3.3	3.6	—0.3	p = 0.02
	(ii)	36	3.6	3.4	0.2	N.S.
<i>Tests probably related to introversion-extraversion</i>						
1. Accuracy—						
(a) Letter cancellation (number of errors)	(i)	36	12.0	5.0	7.0	p = 0.01
	(ii)	36	9.0	4.0	5.0	p = 0.01
(b) Track tracer (number of errors)	(i)	36	13.0	7.0	6.0	p = 0.01
	(ii)	36	13.0	7.0	6.0	p = 0.01
(c) Porteus mazes (number of blind alley entries, once)	(i)	34	7.3	5.1	2.2	p = 0.01
(d) Porteus mazes (number of blind alley entries twice)	(i)	34	1.4	0.2	1.2	p = 0.01
<i>Tests probably related to general intelligence</i>						
1. Raven's matrices	(i)	36	34.0	38.0	—4.0	p = 0.01
2. Vocabulary (number correct, Terman, 1916)	(i)	36	68.0	73.0	—5.0	p = 0.01
<i>Tests probably related to psychoticism</i>						
1. Tempo (preferred)—						
(a) Counting forwards (time in sec)	(i)	36	13.5	14.0	—0.5	N.S.
(b) Counting backwards	(i)	36	20.5	21.0	—0.5	N.S.
(c) Reading easy prose	(i)	36	156.0	156.0	0.0	N.S.
(d) Reading difficult prose	(i)	36	128.0	135.0	—7.0	N.S.
(e) Dressing (time in min)	(i)	18	6.5	5.0	1.5	N.S.
(f) Undressing	(i)	18	12.0	9.0	3.0	N.S.
2. Fluency—						
(a) Tests of verbal fluency (number of responses in one min)	(i)	36	15.0	22.0	—7.0	p = 0.01
	(ii)	36	21.0	35.0	—14.0	p = 0.01
	(iii)	36	16.0	25.0	—9.0	p = 0.01
	(iv)	36	3.0	5.0	—2.0	p = 0.01
(b) Drawing test of fluency	(i)	36	11.0	13.0	—2.0	p = 0.01

— Changes in the direction of decreased neuroticism, increased extraversion and decreased psychoticism.

No consistent pattern is evident for the cingulectomy group in respect of introversion-extraversion or neuroticism, but a consistent decrease in psychoticism is noted for this group. Of seven scores defining this latter factor for the cingulectomy group only two changes reach statistical significance.

An examination of Petrie's work in detail will reveal many of the defects of pioneering studies, an enthusiasm that occasionally prompts the drawing of conclusions not strictly warranted by the data at hand being one of them, but the fact that her work represents the first thoroughly systematic attack on the problem of describing the behavioural changes after psychosurgery gives it a merit which must override all other characteristics it possesses.

Two other workers in the field of psychosurgery, one preceding that of Petrie and the other following it, have utilized similar objective tests, although neither has employed them in the systematic way in which Petrie has done. The earlier of these, Rylander (1939*a* and *b*, 1943, 1947, 1951), must be credited as being the first in the field of psychosurgery who applied objective tests in an effort to describe personality changes. Both Petrie and Tow have referred to Rylander's work extensively and we do not propose to repeat their comments here.

The work of Tow (1955) is in the same tradition as Petrie and Rylander. Like Petrie, Tow was careful to choose his subjects from amongst those patients suffering from "functional disorders," subjects who were not so ill as to yield equivocal scores on performance test. His subjects received a blind orbital type operation and were tested before and after operation at intervals similar to those employed by Petrie, with the difference that Tow tested post-operatively at one year. He saw thirty-six subjects in all.

Despite surprisingly little reference to Petrie's monograph, Tow administered many of the same tests. We have arranged his results in Table XV.3, to facilitate comparison between the two bodies of work, so that the scores of tests which are either the same or similar to those defining the personality dimensions in Petrie's table (XV.2) are grouped together. Under neuroticism may be grouped a number of speed of performance measures, four measures of disposition rigidity, two of persistence and one measure of the number of "troubles" ascribed by the patients to themselves. Under introversion-extraversion may be grouped four measures of accuracy, two Porteus Maze measures of Blind Alley entering, and the comparison of the change after operation between a performance test of intelligence and a verbal test. Under psychoticism may be grouped a number of measures of tempo (preferred) and of fluency. Detailed descriptions of these tests will be found in Tow's monograph.

Clearly no exact comparison is possible since the

tests used have not been exactly the same in all cases but, nevertheless, it is instructive to consider the pattern of changes for this group of patients, as was done for Petrie's subjects. Three of the changes that we have grouped under neuroticism changed significantly although not in the same direction. All of the measures of speeded performance tended to show a reduction in speed (except the speed score on the Track Tracer), one measure of disposition rigidity changed towards increased rigidity and both measures of persistence showed a decrease in persistence. These scores suggest, if anything, an increase in neuroticism.

In the absence then of significant and completely consistent changes, no change towards decreased neuroticism is evident for this group, on the contrary there is more evidence for an increase in this factor.

All the tests which we have grouped under introversion-extraversion changed significantly and all of them, except the comparison of the two intelligence measures, towards an increase in extraversion. The comparison of the two intelligence scores is probably not particularly similar to the comparison Petrie made, since the Raven's Matrices is hardly a performance test in the same way as the Performance Scale of the Bellevue-Weschler Test.

Of the tests grouped under psychoticism, the measures of preferred tempo show no consistent trend nor are any of the changes significant ones. Contrary to Petrie's results all of the measures of fluency used by Tow showed significant changes after operation and, in terms of the dimensions employed by Petrie, all are in the direction of increased psychoticism.

Conclusions from the Factorial Studies

If we can be permitted the licence of considering these two studies together we can conclude—

(*a*) The most consistent changes are evident after standard lobotomy and rostral lobotomy, both towards indications of amelioration of psychiatric disturbances, and decreased introversion.

(*b*) The pattern of changes for the selective procedures reveals no clear trend but a decrease in introversion is evident in the scores of both groups of patients.

(*c*) Whether the amelioration of psychiatric disturbances, as indicated by changes in neuroticism and psychoticism, occurs after the selective procedures is uncertain. The two studies returned opposing findings for these factors in the sense that Tow's group appeared to have had a higher degree of psychoticism after operation than before.

These conclusions are to be thought of as suggestive only. The assumptions the foregoing treatment makes about the comparability of tests and what they

measure are too tenuous to make decisive claims but, in general, it would appear that a reasonable summary of the two sets of findings would be that the question

of whether changes in neuroticism or psychoticism occur remains unanswered but that the change towards increased extraversion is consistently evident.

STUDIES OF COGNITIVE CHANGES AFTER FRONTAL LOBE LESIONS IN ANIMALS AND PSYCHOSURGERY IN HUMAN SUBJECTS

Two influences have joined to make the study of cognitive changes after psychosurgery relatively much further advanced than those of personality with which we have so far been concerned. Firstly, the history of mental testing, with its tradition of objectivity, is a long one and has given rise to relatively well validated and reliable measures of intellectual capacities. Secondly the popular belief (probably at least partly without foundation) has been that increasing cognitive abilities (culminating in man) are related to the growth and complexity of the frontal cortex. Thus, runs the argument, any insult to these areas is likely to result in intellectual deficits and such deficits, or rather, such putative deficits, have prompted a large number of studies both in the comparative field and with the subjects of psychosurgical operations. Much of the animal work has also been directly concerned with the identification of the functions of the frontal lobes, as have some of the studies with humans, although these inquiries have usually been made incidentally within studies whose principal aim has been to assess the effects of a psychosurgical procedure.

Cognitive Changes after Frontal Lobe Lesions in Animals

An excellent general review of this topic has been presented by Chow and Hutt (1953); we intend to stress those studies, particularly the more recent ones, which bear directly upon the question of whether any intellectual deficits may be expected after psychosurgery. We will, as before, confine ourselves mainly to studies on the primates, those animals whose central nervous systems most closely resemble that of man. Even here the hazards of generalizing from one phylogenetic level to another are only too evident. One of the best established findings in the literature on frontal lobe lesions in primates is that while simple discrimination problems are not affected by lesions, delayed response and delayed alternation response type problems are, most markedly, so affected. There has been no such precise definition of a deficit obtained with human subjects in purely cognitive functions.

Historically, perhaps the most important workers in the field of animal extirpations and their effects upon behaviour have been Bianchi (1922) and Lashley (1929). The workers we will be largely con-

cerned with are, Jacobsen and his associates, Harlow and his associates, and Mishkin and Pribram and their associates. The animals involved in these studies have been commonly, rhesus monkeys, the species *macaca mulata*, baboons and chimpanzee. The tasks that have been commonly employed are --

(a) *Instrumentation*: the need to use, say rods, to obtain some goal object.

(b) *Sensory discrimination*: learning to choose one of two objects on the basis of some sensory difference; e.g. colour, form, roughness, etc.

(c) *Delayed response*: the animal is shown some goal object; the object is concealed in some way from the animal's view and, after a delay with the object out of the animal's sight, the subject is required to choose or identify the object.

(d) *Delayed alternation problems*: similar to (c) except that the animal has to reject the object indicated, after a delay, and is required to choose an alternative object that has been presented simultaneously, but not indicated.

(e) *Conditional reactions*: usually some variant of ordinary instrumental conditioning.

That the identification of frontal lobe functions is a dominant feature of these comparative studies, is evident from the earliest work. Jacobsen, for example, investigated the effects of frontal extirpations on monkeys in a series of experiments in the two decades from 1920 to 1940. He came to the conclusion that his results were in line with those of Brickner (1936) —that the deficit resulting from frontal lesions lay: “. . . in the synthesis into complex structures of the simpler engrammic products associated in the more posterior parts of the brain.”

It is a little difficult to see just what is meant here and, in fact, such generalizations have tended to drop out of the more recent literature. Jacobsen himself (Jacobsen *et al.*, 1935) stays much closer to the data when he concludes from a series of extirpation studies that: “. . . after injury to the frontal association area, those activities which demand an integration over a period of time can no longer be effectively carried out.”

On the basis of their numerous investigations into the effects of extirpations in monkeys, Jacobsen and his associates come to a number of more specific

conclusions (Jacobsen, 1935; Jacobsen *et al.*, 1935; Jacobsen and Nissen, 1937)—

(a) Delayed response and delayed alternation type tasks show the most marked deficits after frontal lesions.

(b) Little or no deficit follows lesions on discrimination or instrumentation type tasks, unless they require temporal integration.

(c) The deficits of (a) are definitely associated with lesions in the frontal lobes since lesions in other areas (e.g. the parietal and occipital lobes) do not produce such deficits and unilateral frontal lesions produce less pronounced deficits than do bilateral lesions.

A great deal of the later work in this field has been directed towards testing and refining these findings. The work of Harlow, for example, overlapping that of Jacobsen, is very largely concerned with elaborating and duplicating his investigations. Harlow and Dagnon (1943) compared four bilaterally operated animals with six controls on discrimination problems. They concluded that, contrary to Jacobsen's finding, differences do exist between the operated animals and their controls in point of performance on this type of task although, with additional training, the former group could be raised to the level of the latter. Spaet and Harlow (1943) developed various delayed response problems that retained the essential feature of temporal delay while differing in make-up from the tasks used by Jacobsen. They used, for example, an interrupted "matching from sample" technique which required the animal to choose an object similar to one shown before a delay while a "sample" object remained in view during the delay. They employed also non-spatial delayed response problems where the choice objects had to be distinguished on other than purely spatial grounds and found, for all these variants, that their experimental groups performed as well as their controls.

These results of Harlow and Dagnon, and Spaet and Harlow are contrary to those of Jacobsen and his associates. The former writers account for these differences in findings by claiming that Jacobsen's animals were not allowed to form the crucial associations prior to the delay sufficiently well. They further conclude from their studies that no single ability seems to be destroyed in monkeys by frontal lesions and that when deficits in delayed response tasks are observed, they could be due to any of a number of factors; loss of speed of learning, loss of the effectiveness of the expected reward, etc. Harlow and Johnson (1943) provided an important control observation for these and all extirpation studies on the frontal lobes of monkeys, when they showed that operated monkeys would initiate behaviour to food when no new

associations were required to be formed, to the same extent as non-operated monkeys.

Harlow and Spaet (1943) and Campbell and Harlow (1945) modified the contradiction of Jacobsen's work somewhat and conceded that there was a characteristic deficit following frontal lesions in monkeys on delayed-response type problems, although they still emphasized that the operated monkeys could be trained readily to the level of the relevant control group, showing that the loss was not an absolute one. They also carried out further control studies which showed that test history, length of interval from operation to testing and the extent of lesions within the frontal lobes, had little effects upon the results. It should be noted that all the lesions employed in these studies were relatively extensive.

Campbell and Harlow (1945) summarize their findings as follows—

following the destruction of the frontal and pre-frontal association areas, (monkeys) suffer a deficit in attending and fixating limited aspects of a test situation and this operates to reduce the effectiveness of the acquisition of complex problems such as the delayed reaction.

A summary of the earlier work of Harlow and his associates is to be found in Harlow and Settlage (1947) in which summary a wide variety of deficits, following frontal lesions in monkeys, are reported. The more recent work of these writers tends to be confusing. Contrary to the earlier finding of Harlow and Spaet, and Campbell and Harlow, Warren and Harlow (1951) showed that posterior lesions were more deleterious than more anterior ones. Harlow *et al.* (1952) cast a doubt on this revision by reporting that animals with anterior lesions tended to be poor on delayed response tasks but that animals with more posterior lesions were adequate on these tasks but poor on discrimination problems at which the former group had been adequate.

Finan (1939, 1940) analysed another important aspect of Jacobsen's work when he investigated whether the deficit associated with delayed response tasks was due to the absence of differentiating cues at the test choice-point, or whether the deficit only occurred "where the degree of influence exercised by repeated training in the establishment of their (i.e. the differentiating cues) corresponding habit is minimal." This suggestion is clearly similar to that made later by Spaet and Harlow, and Harlow and Dagnon that the animals in Jacobsen's study had not been allowed to form the relevant associates sufficiently strongly. Finan studied the performance of a group of operated monkeys on—

(a) A task which required the subject to move from one compartment of a cage to another, ten

seconds after the raising of a dividing door; shock followed too early or too tardy reactions.

(b) A task where of two maze paths, one having a thirty-second delay chamber, the other a one hundred and twenty-second delay chamber, the first had to be learned.

(c) Delayed response tasks similar to Jacobsen's.

It will be observed that in both (a) and (b) the elements of delay are retained but the animal has constantly before him differentiating cues. Finan reported that there were no deficits in these two tasks but confirmed Jacobsen's finding that type (c) problems result in considerable deficits.

Wade (1947) also reported an important finding when she was able to show that injections of Nembutal (a sedative) into post-operative monkeys reinstated their capacities to perform delayed alternation tasks. Pribram (1950) repeated the observation in a study in which he examined the performance of a group of baboons who, over a period of six months, had shown consistently poor performances on delayed response tasks and were then subjected to a number of experimental conditions. One of these, the injection of Nembutal, confirmed Wade's finding. Pribram also reported that insulin, reduced environmental temperature and fasting resulted in improvements on the delayed response tasks, while no improvement resulted from the injection of Benzedrine, from increased environmental temperature or pre-feeding. Pribram's findings in this study, if nothing else suggest that no one factor of environment is crucial for the appearance of the deficit and that it is likely to occur only under quite precise conditions.

Blum *et al.* (1951) repeated Wade's and Pribram's investigation of the effects of Nembutal on delayed response task deficits and were unable to report their confirmation. Blum *et al.* suggested that improvement had occurred in the animals of the earlier studies because they had been tested at relatively short intervals after operation and had not performed better than chance during the initial post-operative period. The animals of Blum's *et al.* study differed from the subjects of the earlier studies in both of these respects and no improvement following Nembutal was observed.

Mishkin *et al.* (1953) proceeded from the above suggestions of Blum *et al.* and tested animals, at more than six-monthly intervals after operation, and which had scored above chance on delayed response tasks post-operatively. They concluded that improvement did in fact follow the injection of Nembutal, although they conceded that considerable re-training was required.

Wade (1947) had based her argument as to why any improvement in performance should follow the injection

of Nembutal into post-operative monkeys on a suggestion of Malmö. Malmö (1943), subscribing to an interference theory of forgetting, suggested that the failure of operated animals upon delayed response tasks might be due to their being more liable to interference from irrelevant stimuli during the delay. Wade proposed that the administration of a sedative, depressant drug, would reduce the effective strength of these stimuli and so result in an improvement on the problem tasks.

It is worth noting at this point that, recently, Summerfield and Steinberg (1958) have made a similar observation with human subjects learning nonsense syllables. These authors required a group of subjects partially to learn lists of nonsense syllables then interrupted the learning process. During this interruption, employing appropriate controls, they administered nitrous oxide while the subjects were engaged in various tasks. They found that the administration of this depressant, nitrous oxide, significantly reduced the degree of forgetting evident during the subsequent resumption of the learning task. Their account of their findings is also in terms of the reduced efficacy of interfering stimuli during the interpolated interruption period, after the administration of the depressant drug.

The data on the effects of sedatives on performance after frontal lesions, in so far as they can be accepted, are relevant to the hypothesis we have suggested concerning the nature of the change frontal damage brings about. Because of the nature of the neurological parameter postulated as underlying introversion-extraversion, the relatively more extraverted person would be expected to be particularly prone to the effects of retroactive inhibition of the type analogous to that being proposed as responsible for the deficits in the performance of leucotomized monkeys on delayed response tasks. Since we have suggested that frontal lesions result in an increase in extraversion, the demonstrated deficit is thus consistent with this notion, as can be seen. If the hypothesis about an increase in extraversion following frontal lobe lesions were correct, and if the general hypothesis about the nature of the underlying neurological parameter of introversion-extraversion were also correct, then the found effect of Nembutal on delay response tasks would be expected. The finding forges another link in a nomological chain.

A great deal of the work of Mishkin and Pribram and their associates has also been concerned with analysing the putative deficit following frontal lesion in monkeys performing delayed response tasks. One general conclusion from their work confirms earlier findings in that they claim that the deficit tends to be maximal when the traditional left-right choice is used (*see also* Finan, 1940; Spaet and Harlow, 1943).

The various investigations of Mishkin and Pribram and their associates have resulted in these conclusions (Mishkin and Hall, 1955; Mishkin and Pribram, 1955; Pribram and Mishkin, 1955; Mishkin and Pribram, 1956; Pribram and Mishkin, 1956)—

(a) deficits follow when, instead of being placed side by side, the choice cups are placed one above the other;

(b) deficits follow when a "go-no-go" type of alternation is required;

(c) the deficit is definitely linked to lesions in the frontal lobes, since control groups with lesions in the infero-temporal region were able to perform the task adequately;

(d) the size of the deficit varies as some function of the stimulus conditions; for example, a group of frontal animals performed the task nearly as well as controls "whenever a single cue presented in one of two places was replaced by one of two cues presented in a single place." (Mishkin and Pribram, 1956.)

The basic observation of a deficit following frontal lesions has been studied in the light of various control situations some of which remain to be mentioned.

Forays (1952), in a very important investigation, tested rats in a closed field apparatus at varying intervals after cerebral excisions had been made. He found that no drop in performance occurred if testing was carried out within two hours after operation. After this he reported the usual sharp decline in performance. Contrary to Jacobsen *et al.* (1935) he claimed that lesions in the parietal lobes seemed to be of importance for this task.

The important feature of Foray's investigation is not this latter finding, of course, but the implication from the former that some rapidly occurring biochemical change or degenerative process following excisions might be responsible for the changes after frontal lesions.

Orbach (1956) has pointed out that the artificial production of the toxic action of cell degeneration and the mechanical distortion produced by pressure or diaschisis have not resulted in deficits in performance and he therefore doubted Foray's results. In his own study, four monkeys were trained on delayed response tasks and trephine holes made. The animals were tested immediately after this procedure and for a further ten to fourteen days when frontal lesions were made "blind." The animals were then tested again between one and a half to six hours after the operation and for a further fourteen days. Orbach reported that no drop in performance followed the trephining procedure but that immediate deficits appeared after the introduction of frontal lesions,

which deficit decreased with further testing but performance never reached the pre-operative level.

The discrepancy between the results of Forays and Orbach may be due to either a difference connected to the different types of tasks employed or to a difference in response to injury of the more complex primate cerebrum.

Pribram (1955) demonstrated that the deficits were not due to lesions in the frontal eye-fields or due to the scarring of these areas, although he believed that the former were certainly somewhat involved in the production of deficits in delayed response tasks after frontal lesions. In his study monkeys were trained on visual pursuit tasks, visual discrimination tasks, visual field tests and delayed response tasks. Lesions were introduced into the frontal eye-fields, either surgically or by the implanting of ammonium hydroxide pastes which resulted in scarring of the tissues. Only the delayed response tasks were affected, showing that primary visual abilities were not the cause of the deficits. Scarring produced only slight temporary effects while the surgical lesions produced somewhat more marked deficits in performance on the delayed response tasks. Pribram concludes that the deficits he observed in this study were much less severe than those seen after anterior operations and could thus not be wholly responsible for deficits found after the latter.

Miles and Rosvold (1956) provided another control study when they showed that the deficit in delayed response behaviour of monkeys occurred whether the motivating conditions were food or electric shock.

One final study should be mentioned; that of Rosvold and Delago (1956). They implanted electrodes in various parts of the cortices of four *macaca mulata* monkeys and observed the effects of electrical stimulation and destruction by coagulation of these areas on visual discrimination and delayed response tasks. They found no consistent difference between the various effects of stimulation and coagulation but noted that the destruction of the *corpus striatum*, particularly of the caudate nucleus and its cortical projections, most regularly resulted in the changes in activity and gastronomical disturbances that have usually been ascribed to leucotomy and psychosurgical procedures in general. Miles and Rosvold, in the study quoted above, also concluded, after histological examination, that the caudate nucleus might well have been involved in the changes observed by them.

Conclusions from Animal Studies

As we pointed out at the beginning of this section, there is no necessary warranty for arguing from one phylogenetic level to another. If, however, we wish to apply these comparative findings to the cases of

psychosurgery performed on human subjects, we could conclude that—

(a) a deficit in cognitive abilities, following psychosurgical procedures, might not be an absolute one, in the sense that manipulation of the form of the problem material could result in the disappearance of the deficit;

(b) the evidence, from these sources, as to whether degenerative biochemical processes or by-products result in cognitive deficits rather than the mere severing of tracts being responsible is inconclusive but generally does not support the first alternative;

(c) no deficit can definitely be ascribed to the frontal areas since, notwithstanding (b), some evidence points to the involvement of supracortical areas being involved, perhaps through neural degenerative processes.¹

Cognitive Changes after Psychosurgery and Theories of Frontal Lobe Functions

Cognitive changes after psychosurgery in psychiatric patients have most usually been investigated with the very practical aim of describing what are essentially side-effects, albeit important ones, of the operative procedures. Most theories of frontal lobe functions have been based on the study of brain damage resulting from natural causes and, although these have been dealt with extensively in the preceding chapter, several of the most important should be mentioned here, as a preliminary to our discussion of cognitive changes, because they have influenced the nature of the assessments of these changes in psychosurgery patients.

THEORIES OF FRONTAL LOBE FUNCTIONS

Bricker's (1936) belief that his lobotomized patient had lost the capacity to compound simple patterns into more complex ones has already been mentioned. His work was based on the extensive study of a single case who had a bilateral removal of the frontal tissue for the extirpation of frontal neoplasms.

Goldstein (1939, 1949; Goldstein and Scheerer, 1941) initiated a widely accepted characterization of frontal lobe functioning when he concluded that his brain-damaged patients were deficient in their capacity to carry on abstract thought and tended toward a more concrete level of thinking.

Many workers, working with psychosurgery patients, have arrived at similar conclusions to those of Goldstein or have taken his hypothesis as a starting-

point. For example, Nichols and Hunt (1940) in another extensive study of a single case of frontal lobectomy, reached a position similar to Goldstein's when they described the deficit shown by their patient (in the presence of high intelligence test scores) as being composed of four aspects—

(a) the failure to supply spontaneously, fresh modes of attack on a problem, apparently resulting from an inability to abstract that aspect of the situation causing the difficulty;

(b) a rigidity of the "categorical attitude";

(c) a sharp limitation in the number of lines of endeavour able to be kept separated simultaneously;

(d) an inability to integrate several aspects of a situation.

When we come to deal with specific test results, we will mention a fairly consistently reported finding that after psychosurgical procedures there is a fall in Porteus Maze scores. Porteus has, on the basis of this, offered a theory as to the nature of frontal lobe functions. He has claimed that his test measures planning ability and has thus characterized the change in behaviour after psychosurgery as being in this function. We would like to mention two, rather lengthy, papers which treat of this proposition directly.

Porteus and Kepner (1944) reviewed the previous work on the Maze Test performance of psychosurgery patients and examined in detail the case notes of some twenty patients of mixed diagnoses who had been subjected to psychosurgical procedures. They noted that Binet scores showed no consistent changes after operation but that the lack of any increase from the pre-operative to the post-operative score on the Maze tests, indicated that the performance of the patients on the second occasion was deficient, since the Maze Test shows a large practice effect. These authors concluded that the lack of foresight and initiative, those capacities believed to be measured by the Maze Test, did indeed seem to comprise the deficit after the operations.

Porteus and Peters (1947), however, preferred to start from the other end. They observed that it is well known that psychosurgery results in a lack of foresight and initiative. This fact they perceived as a golden opportunity to validate the Maze Test which purports to measure these faculties. They compared the scores of fifty-five leucotomized patients tested on five different occasions and compared them with the scores of a group of non-operated prisoners. The post-operative patients proved once again to be inferior on this test and accordingly, the authors concluded that the Mazes do in fact measure planning ability.

The suggestions for the nature of frontal lobe

¹ Yokoi (1957) has summarized much of the work done on the degenerative processes after psychosurgery and he concludes, after the examination of a number of specimens himself, that widespread degeneration is evident extending to various supracortical bodies.

functionings of both Goldstein and Porteus, it can be seen, are both based on performance deficits in quite special tests and the question of what in fact the tests do measure is crucial for the acceptance of these suggestions.

Payne (see Chapter 6) has presented a most damaging set of criticisms of Goldstein's notion of abstraction and of the tests which purport to measure it. If one accepts these criticisms, it becomes evident that the matter of whether psychosurgery patients show any deficit in concept formation has never been properly tackled. It seems to the present writer that an application of the procedures described by Bruner *et al.* (1956) would meet Payne's criticisms, as they apply in the case of psychosurgery's effects, and could well reveal important deficits in concept formation for patients so treated.

The function measured by the Porteus Mazes is of considerable importance since, as we shall see, decreases in performance on this test do regularly follow from the introduction of frontal lobe lesions. In fact the evidence points to the Mazes not measuring some purely cognitive factor at all but rather reflecting some personality variable—probably the willingness or capacity to follow instructions. Porteus's original work was with groups of psychopaths (1923, 1933, 1942) who regularly scored below normal groups. This finding has been repeated many times (Wright, 1944; Docter and Winder, 1954; Purcell, 1956; Fooks and Thomas, 1957). That such groups should be characterized by a purely cognitive deficiency seems unlikely and in fact has never been demonstrated. That they are characterized by a high degree of extraversion has been shown a number of times (Hildebrand, 1953; Franks, 1954; Lykken, 1957). Moreover, Hildebrand (1953) has shown that the test differentiates between groups of psychiatric patients—those who would be regarded as possessing higher degrees of extraversion having lower scores (Q scores). In view of these considerations, then, we are inclined to reject the notion that the Mazes measure only foresight or planning ability and to suggest that they reflect introversion-extraversion. The consistently reported decrements on Maze scores following psychosurgery strongly support the contention that the predominant change after psychosurgery is in the direction of increased extraversion, if this interpretation of what the Maze Test measures can be accepted.

Halstead (1947a; Halstead *et al.*, 1946) is another who has tried to specify what function is subserved by the frontal lobes in his own terms and by the employment of performance tests. He has presented the notion of "biological intelligence," a function which is measured by an "impairment index" and which was developed in view of the consistently negative findings of investigations measuring general intelligence by

orthodox means in groups of brain-damaged and post-leucotomy patients.

The concept of biological intelligence is rather vague, even amongst those notions associated with the effect of psychosurgery. The function is regarded as being connected with the "ego" or with some mechanism reflecting the degree of integrity of the central nervous system. The impairment index is derived by counting how many of ten brain-damage indicators yield scores similar to those given by groups of brain-damaged patients. The battery of tests defining biological intelligence was administered to a group of brain-damaged patients including eight post-leucotomy patients (Halstead *et al.*, 1946). According to the notion implicit in Halstead's account the operation should have interfered with the degree of integrity of the central nervous system and the psychosurgery patients should have showed a drop on the impairment index. In this study, however, they did not, although a group of lobectomized patients was differentiated from a control group.

Although Halstead's idea is an interesting one, it presents certain difficulties. For example the reliability and validity of his defining tests have never been satisfactorily established, and a number of them would seem to be intercorrelated, so that, in fact, something less than ten separate measures probably go to make up the "index." Adding the various components together, while in itself a rather dubious procedure, would at best result in a measure of a relatively narrow and undefined band of capacities.

Reitman (1955a) has attempted a validation of this notion of Halstead's in a rather strangely convoluted study. He administered the battery of index tests to fifty mixed brain-damaged cases together with ten criterion tests, culled from the literature as being good indicators of brain damage. He reported that the index tests discriminated the brain-damaged group from a control group better than did the criterion tests. The latter included a test of critical flicker fusion, a modified version of the Seguin Form Board and the rhythm subtest of the Seashore test of Musical Aptitude.

One can see that his results are favourable to the claims of the impairment index but the assumption that the criterion tests were indicators of brain damage cannot be passed undebated and, since one of these, a test of categorizing, was as good as the impairment index tests at discriminating the brain-damaged cases, one cannot see the point of employing them in its stead.

Notable physicians have frequently suggested a number of characterizations of the deficits believed to follow psychosurgery. Freeman, for example (1942) at first proposed a notion very similar to that we discussed in association with Porteus (see also Porteus,

1951, 1955), who refers to Freeman as his source in this matter. Freeman at first suggested that the frontal lobes were concerned with foresight and planning. In later writings (Freeman and Watts, 1950; Robinson and Freeman, 1954) Freeman generalized this concept somewhat and concluded that the awareness of self in time is the concern of the frontal lobes—they are concerned in the person's perception of his own continuity through the course of time.

Landis *et al.* (1950) and Mettler and Landis (Mettler 1952) have suggested two characterizations of the frontal lobe functions in cognition—

(a) the span of attention of the post-psychosurgery patient is decreased and he is typically "stimulus-bound";

(b) in the post-psychosurgery patient the most notable feature is a general weakening of stimulus bonds.

It will be noticed that (a) has something in common with one of the conclusions arrived at by Greenblatt and Solomon in reviewing the effects of their operated cases and could be supported by some of the findings with monkeys on delayed response tasks. In general, however, none of these formulations can command a great deal of respect. They tend either to be so narrowly associated with some specific test as to be virtually untestable other than by reference to that test or so vague, like the suggestions of Landis *et al.* or Freeman, as to be virtually incapable of disproof.

COGNITIVE CHANGES

If we now turn to data from the application of cognitive tests to psychosurgery patients, we will be impressed with the general agreement that very little change in fact ensues after these operations. This was the kind of observation that led Halstead and others to conclude that the wrong tests were being used. There is, of course, no *a priori* reason for supposing that any intellectual deficits should follow circumscribed lesions in the frontal lobes, but our view is that the matter has not been decided and, in substantial agreement with Halstead, we believe will not be decided until a thorough revision of the nature of the cognitive processes has been made. The beginnings of such a revision will be found described in chapters in this HANDBOOK by Payne and by Furneaux. We will not attempt to reproduce their arguments and the reader is referred to the relevant chapters for this information. We will simply report a selection of the findings on cognitive tests that occur in the literature on psychosurgery, without necessarily accepting the interpretation of what the tests measure usually included in these reports.

Rylander, as has been mentioned, was one of the first to administer objective tests to psychosurgery

patients and he has been very much concerned with the question whether general intelligence is decreased after these operations. He has summarized his results and has illustrated his case with detailed notes on eight neurotic patients (Rylander, 1947), concluding that there is a consistent drop in intelligence as measured by the Terman and Merrill revision of the Binet Scales. Malmo (1948) reported significant drops in Wechsler-Bellevue and Stanford-Binet vocabulary scores for eight patients subjected to leucotomies and seven undergoing gyrectomies. Koskoff *et al.* (1948) reported the testing of some of ten patients subjected to a psychosurgical procedure for the alleviation of pain and found a significant decline in Wechsler-Bellevue scores. Petrie (Petrie, 1952; Petrie and Le Beau, 1956) reported a similar finding for her groups subjected to rostral procedures and standard lobotomies but found no significant changes after any of the selective procedures she examined. Tow (1955) found a significant drop in scores on Raven's Matrices and the vocabulary test from Terman's 1916 battery. Tow's patients had been subjected to a procedure similar to those employed with Petrie's earlier groups. Yacorsinski *et al.* (1948) administered a large battery of tests to a single patient and reported a drop of eighteen points on the Wechsler-Bellevue scale.

These positive findings, however, are in a minority and the more usual report is of no decrement in general intelligence as measured by orthodox means. None of the large-scale studies of the Columbia Greystone or New York Associates or those from the Boston Psychopathic Hospital contain mention of permanent deficits indicated by alterations in either Wechsler-Bellevue or Stanford-Binet scores. Likewise, the investigations of Robinson (1946), Frank (1946), Carscallen *et al.* (1951), Crown (1952), Markwell *et al.* (1953), Struckett (1953), Medina *et al.* (1954), Hirose (1954), Wideman (in Miller, 1954) and Newman (1955) were more or less negative in respect of this class of change.

A number of writers have tried to analyse putative deficits by subtests. In general, these efforts have produced no consistent findings, but a direct attack on the problem has been made by McCullough (1950). He administered Form I of the Wechsler-Bellevue Scales to twenty-one patients undergoing psychosurgery, testing on three separate occasions. McCullough reported that the most prominent changes were seen in Digit Span, Picture Arrangement and Block Design subtests while no change occurred in Vocabulary, Information and Similarities. Medina *et al.* in the study mentioned above have reported a specific deficit on the Picture Arrangement subtest. Although Wideman, also quoted above, was unable to demonstrate any deficit following operation, he reported, on analysing his subtest scores, that clinical improvement

seemed to be associated with a higher Performance than Verbal score, a small degree of Performance "scatter" and relatively high scores on Picture Arrangement, Picture Completion and Similarities.

Tow's use of Raven's Matrices has already been mentioned and the fact that he found a significant deficit on this test after leucotomy operations. Previously to this study, neither Frank (1946) nor Struckett (1953) found any fall in scores on this test with psychosurgery patients.

It has been mentioned that many writers have reported utilizing Goldstein's suggestion that abstract reasoning is affected by frontal lobe damage. King (in Mettler, 1949) made an important contribution towards testing this notion in the field of psychosurgery when he administered seven different tests, purporting to measure abstract reasoning ability, to seventeen operated cases and thirteen controls. He carried out a factor analysis of the subjects' scores on these tests and on tests of general intelligence. His conclusion was that the tests of "abstract reasoning" were highly saturated with a factor of general intelligence and that no significant differences between the operated cases and the controls, could be demonstrated. Vidor (1951) also reported a high correlation between performance on sorting tests and tests of general intelligence. Sheer and Shuttleworth (in Mettler, 1952) reported a temporary deficit on the Weigl Sorting Test and on a revised Homograph test for the group of subjects of the second Columbia Greystone project, while Sheer (in Lewis *et al.*, 1956) confirmed the finding of a deficit but once more stressed its temporary nature.

Neither of the two reports from the Boston Psychopathic Hospital made any material contribution towards this problem. Atwell in the first report (Greenblatt *et al.*, 1950) administered Goldstein's Block Design and Colour Sorting tests, the Weigl Colour-Form Sorting Test and the Shipley Test of Abstraction. He decided that none of the tests were suitable for proper quantification and was content to make a qualitative judgement about post-operative changes. Upon the basis of these judgements he reported a slight decrement in performance on these tests. In the second report (Greenblatt and Solomon, 1953), Levinson *et al.* administered a number of tests of Abstract-Reasoning and of "Coherence of Association" and reported on "improvement" in their subjects, particularly in the "emotional forms of the abstraction tests" (proverbs and similarities). Supporting this claim they point out that the most clinically improved patients seen by them showed the most improvement on the test of abstraction. In so far as the interpretation of these results can be accepted, they are somewhat contrary to others in the field. King's finding mentioned previously, however,

casts doubt on all this work and suggests that tests of abstraction probably measure nothing more than general intelligence.

Certain other investigations have utilized various tests of Abstraction. Kisker (1944a) was able to demonstrate no consistent impairment on a modified version of Koh's Blocks, the Weigl and Scheerer Sorting Test and the Goldstein Colour-Form Test. Likewise Robinson (1946) reported no decrement after operation on the Shipley-Hartford Retreat Scales. Neither Berg and Grant (1948), using a Weigl type sorting test and the Weigl Colour-Form Test, nor Vidor (1951) using various tests of abstract thinking was able to demonstrate any decrement after psychosurgery. Tow (1955) administered a sorting test to his subjects and contrary to the aforementioned reports noted a large decrement after operation, significant at the 1 per cent level of confidence. Tow described the behaviour of his subjects on this test as follows—

After operation the subject is more foolish, naïve and clumsy in his approach. He does not easily grasp the nature of the problem. If there is any plan or reason at all in his method, it is more rigid and stereotyped. The subject looks blank at the examiner's questions and he is more quickly moved to despair and abandonment of further trial. His whole performance is less directed and less purposeful. It is obvious that his ability to sort is greatly reduced. (Tow, 1955.)

Considering, then, tests of general intelligence and of abstraction together it would appear that some deficits may be expected after the more radical operations, as in the cases of Petrie and Tow, where, in addition it should also be pointed out, pre-operative performance has not been clouded by the gross cognitive defects of psychoses. For cases in which the latter defects might be expected to be considerable and for the selective operations, the position is not clear. The evidence, however, does point to there being no gross deficits following on such operations.

The evidence also most strongly suggests that the tests of abstraction are very closely related to tests of general intelligence and it is evident that where deficits are found in the latter (as in the cases of Petrie and Tow) some impairment may be expected to be evident in the scores of the former.

Many investigators have administered tests of memory and retention. Stauffer in the first report of the Columbia Greystone project (Mettler, 1949) compared the performance of nineteen operated cases with thirteen controls on learning and retention of three forms of verbal material (*a*) semi-meaningful paired associates, (*b*) meaningful paired associates and (*c*) verbal directions. She reported no significant impairment. In the second report of these associates (Mettler, 1952), North *et al.* examined memory,

learning, mental set and perceptual tasks, by means of, largely, verbal tests. They reported no impairment of memory or learning. It is interesting to note that these workers attempted to duplicate the delayed-response type tasks used in comparative work but found that no deficits were evident with their human subjects. This discrepancy is not surprising, of course, when one considers the relatively much greater damage done to the primates' cortices. These workers finally suggested that "forced" tempo learning was less affected than "free." The finding is relevant to the discussions of the role of neuroticism in the performance of stressful tasks, to be found in the chapters in this HANDBOOK by Inglis and by Jones. A relatively greater improvement under the stress of forced tempo would suggest that some decrease in the degree of neuroticism had occurred for the subjects of this study. North and Zubin (in Lewis *et al.*, 1956) repeated this investigation and in general returned negative results, only temporary deficits being evident for any of the functions they investigated. One of the few exceptions was that performance on a continuous addition task was sensitive to individual change after the operations. The impairment was not due to a decrease in accuracy but to a progressive decrease in the amount of work done over the fifteen-minute period occupied by the test. Such an increase in work decrement would be expected for a condition which heightened extraversion, by virtue of the increased liability to the effects of cortical inhibition which would be postulated as accompanying the personality change.

Kral and Durost (1953) have analysed the amnesic syndrome in a variety of different categories of brain-damaged patients, including leucotomized patients. Their findings, contrary to those listed above, are that impairment of recent memory and recall are common to all. Their conclusions have rarely been paralleled. Hirose (1954) reported no drop in memory functions in a group of ten psychopaths and five neurotic patients subjected to leucotomies—nor previous to this study did Malmo (1948) nor did Markwell *et al.* (1953) nor Medina *et al.* (1954) using the Wechsler Memory Scales and the Benton Test of Visual Retention. Contrarily again, however, Newman (1955) has reported a significant drop on Wechsler Memory Scales for his group.

Rylander (1939a) examined the ability of his lobectomized patients to learn a list of nonsense syllables and reported some deficits but his methods of testing were crude and his findings correspondingly equivocal. Malmo and Amsel (1949) and Malmo (1948) have examined this function more systematically.

Malmo and Amsel on the basis of the hypothesis of Malmo (1942), predicted that the characteristically bowed rote-learning curve would be more peaked for a group of patients with frontal-lobe lesions. They

argued that associative interference or intraserial interference being more pronounced over the middle items of a list, the rote-learning curves of post-psychosurgery patients should be more peaked if, as Malmo suggested, such frontal lesions lead to an exaggeration of the effects of associative interference. To test the prediction they compared the rote-learning curves of six gyrectomy patients sixteen controls and sixteen

FIG. 15.3. COMPOSITE CURVES SHOWING MEAN NUMBER OF FAILURES AT VARIOUS SYLLABLES DURING LEARNING BY SIXTEEN PATIENTS WITH "CLINICAL ANXIETY," SIXTEEN CONTROLS, FIVE GYRECTOMY PATIENTS, AND H.M. (ONE GYRECTOMY PATIENT WHO APPEARED ATYPICAL) (From Malmo and Amsel, 1949)

cases showing clinical anxiety, derived from the rote learning of eight syllables lists of nonsense syllables.

Fig. 15.3 illustrates the resulting data. It can be seen that the curve of the gyrectomy patients appears more peaked in accordance with the authors' prediction. Had the number of the operative cases been larger, the application of an analysis of variance device would have established this finding in a more formal way than that of inspection. Confirmatory evidence, however, is supplied by Malmo (1948)¹ from data collected on the rote learning of eight bilateral frontal lobotomy patients tested before and after their operations. The data are presented, in this study, in the form of the differential amount of behavioural oscillation evident across the segments of a nonsense syllable series. The behavioural oscillation, being measured in terms of the number of alternations from a correct to an incorrect response, is also a function of associative interference and tends also to be more pronounced over the middle items of a list. That Malmo and Amsel's prediction is confirmed is

¹ This study, appears to have succeeded that of Malmo and Amsel, although the latter appears in the literature at a later time.

suggested by the behavioural oscillation curves shown in Fig. 15.4 where it can be again seen that with the introduction of frontal lesions, the degree of peakedness over the middle items appears to have been increased.

Malmö's hypothesis is a particularization of the one we have proposed concerning the nature of the change following psychosurgery, and the data quoted

FIG. 15.4. COMPOSITE CURVES SHOWING MEAN NUMBER OF OSCILLATIONS OCCURRING BETWEEN THE FIRST CORRECT RESPONSE AND LAST FAILURE FOR SYLLABLES IN EACH POSITION FOR PRE- AND POST-OPERATIVE LEARNING (From Malmö, 1948)

above strongly support our contention. Our terminology would be slightly different—we would prefer to use the term associative inhibition—but our prediction would be precisely the same. We would expect that non-brain-damaged extraverts would show evidence of exaggerated associative inhibition in an increased peakedness of the rote serial position curve by virtue of the nature of the neurological parameter postulated as underlying the dimension introversion-extraversion. Such an increase in the peakedness of the rote serial learning curves of post-psychosurgery patients would have been thus expected if the hypothesis that these patients are characterized by a high degree of extraversion is tenable. The evidence is, of course, in no way conclusive but adds weight to the body of observations supporting our hypothesis about the personality changes wrought by psychosurgery.

One further test, already mentioned in a general way, must be dealt with—the Porteus Maze Test. We have said that changes in this test are perhaps the most consistently reported of all. Apart from the

reports made by Porteus himself and his collaborators (Porteus and Kepner, 1944; Porteus and Peters, 1947; Porteus, 1951, 1955—reviews) deficits have been reported by both studies of the Columbia Greystone Associates (albeit, only temporary ones), by the New York Associates and by Greenblatt and Solomon in the second investigation from the Boston Psychopathic Hospital. Decrements in Maze performance after psychosurgery has been reported by Koskoff *et al.* (1948), Crown (1952)—an insignificant one however—Malmö (1948), Petrie (1952), Medina *et al.* (1954) and Tow (1955).

We have suggested that the function measured by the Porteus Mazes is associated with a factor of temperament—introversion-extraversion, and these consistent findings of deficits in Maze performance after psychosurgery also support our contention that it is extraversion that is altered by these procedures.

Conclusions from Studies of Cognitive Changes

Hebb (1945) in the review quoted at the commencement of this chapter, came to the conclusion that no connexion between any cognitive function and the frontal lobes had been, up to the time of his writing, demonstrated. In concluding this present review we could not presume to consider whether or not we have been dealing with frontal lobe functions, but even limiting ourselves to the more modest attempt to determine whether any purely cognitive function is disturbed after frontal surgery for the relief of psychiatric illness, we can, likewise, reach no very definite conclusions. In general it would appear that—

(a) there is a suggestion in the comparative work that some sort of cognitive deficit can be expected to follow extensive operations, and

(b) this suggestion does receive some support from the examination of cases whose pre-operative state is not so disturbed as to render psychological tests of dubious value and who are subjected to relatively radical forms of psychosurgery;

(c) little deficit appears to follow the more circumscribed forms of these operations;

(d) what functions are disturbed must wait upon the application of cognitive tests, like those described by Furneaux (Chapter 5) whose factorial composition is thoroughly known, and which are integrated with a properly formulated and tested conception of the cognitive processes.

ELECTROENCEPHALOGRAPHIC STUDIES AND MOLAR AUTONOMIC CHANGES AFTER PSYCHOSURGERY

We cannot pretend to attempt an adequate coverage of either of these areas of investigation, lying as they do, somewhat outside the limits imposed by the tech-

niques of psychological investigations, but we would like to mention certain studies which have a direct bearing on some of the points we have been making.

Electroencephalographic Studies

We have noted that the hypothesis suggested by Hebb (1949) for the action of psychosurgery, requires the presence of a hypersynchrony in the firing of cortical neurons. Hebb regards the appearance of large potentials, firing spontaneously, in the EEG records, as evidence for such a hypersynchrony and, in fact many EEG studies have reported such features in the post-operative records of psychosurgery patients. The most usual report is of slow waves of large potential appearing at first across the whole frontal cortex but becoming localized about the lesion sites with the passage of time. It should be noted that an assumption is being made about the accuracy of interpreting the EEG records in all this work, an assumption which some might query.

Reports of findings as described above have been made by Davis (1941), Hutton *et al.* (1941), Cohn (1945), Greville and Last (1947), Stevens and Mosovich (1947), Zigarelli (in Mettler, 1949), Bonako (in Miller, 1954) and by Walter *et al.* (1954). Henry (1950a) and Henry and Scoville (1952) have described analogous findings and have stressed the suppression of fast rhythms in the frontal lobes after psychosurgery and the increase in slow waves of large potential.

Somewhat different observations were made by Wada and Enko (1951), who reported the predominance of arrhythmic waves after psychosurgery and by Lennox and Coolidge (1949) who described the most characteristic change in EEG records after operation, as a $\frac{1}{2}$ –1 c/s baseline sway. Henry (1950b) found no evidence of slow-wave activity in two post-operative transorbital lobotomy subjects.

That some form of hypersynchrony be present in the EEG records of post-psychosurgery patients is one necessary condition for the confirmation of Hebb's hypothesis. A second requirement is that such a hypersynchrony be concomitant with clinical improvement. The evidence here is not at all so consistent. Henry *et al.* (1948) found that decreased low voltage fast activity and an increase in alpha rhythm were associated with clinical improvement, a finding which supports Hebb's hypothesis. Walter *et al.* (1954), however, reported that their clinically improved group was characterized by the appearance of a moderate degree of slow-wave activity in post-operative EEG records but that both high and low degrees of such activity were typical of their little improved group. That the relationship between hypersynchrony and improvement should be a linear one is not a necessary implication of Hebb's hypothesis but the hypothesis would require modification if it was found to be otherwise.

Bonako (in Miller, 1954) in a well-constructed study

of one hundred and twelve leucotomy patients, contrary to the above work, found no relationship between the discovery of slow waves in the post-operative EEG records of his patients and clinical improvement. Nor did he find any general change in the alpha rhythm of his post-operative patients, other than some indication of a tendency towards a concentration of the mean values of alpha rhythms. Additionally, however, Bonako did report a number of signs in the pre-operative EEG records which were statistically related to degree of clinical improvement. The favourable signs were, mean alpha indices in the slow normal range and a lower than average fast frequency content in the pre-operative records; the unfavourable signs were the obverse of these and a poorly organized alpha rhythm.

Levin *et al.* found no relationship between recovery rate and the occurrence of post-operative seizures. One might have expected from Hebb's hypothesis that some such relationship of a very general kind might have been found since the appearance of slow waves in EEG records tends to suggest the likelihood of seizures.

That epileptic conditions, at least of a temporary duration, are common after psychosurgery has been commented upon. The incidence of post-operative seizures is one of the usual statistics accompanying clinical reports but a number of studies which bear directly on the problem may be mentioned here.

Wayne (1952) reported that of eighty-seven leucotomy patients in her study 30 per cent developed post-operative seizures while of twenty topectomy patients 42 per cent developed seizures. Aust-Garcia *et al.* (1954) reported that epileptiform activation was common after Poppen-type prefrontal leucotomy and Klotz (1955) reported that of one hundred and ninety-three patients subjected to pre-frontal leucotomies, 19 per cent had grand mal seizures post-operatively whereas only 8 per cent had evidenced them pre-operatively. Klotz found no significant relationship between EEG records and the development of seizures but found that pre-operative E.C.T. treatment was associated with the post-operative development of seizures. Levin *et al.*, quoted above, had made the same observation while Liddell and Rettersol (1957) have reported that treatment with chlorpromazine predisposed patients to develop post-operative seizures after psychosurgery.

Summary of Electroencephalographic Studies

(a) There is some suggestion from a mass of contradictory evidence that some features of the post-operative EEG records reflect a concomitant of clinical improvement, and

(b) The appearance of slow-wave activity in the EEG records would seem to be the most prominent

abnormality evident and may be that feature of the records which is related to improvement. But it is also evident that the relationship is not a simple one.

(c) Certain other forms of psychiatric treatment, E.C.T. and the administration of chlorpromazine appear to predispose patients to the development of seizures after psychosurgery.

(d) The appearance of seizures does not appear to be related to clinical improvement.

Molar Autonomic Changes after Psychosurgery

Wenger (1947, 1950) has produced a considerable body of work which relates a state of autonomic imbalance to emotional lability and, as we have described earlier, Eysenck (1947, 1952) has invoked these studies in support of his notion that the neurological substructure underlying neuroticism is just such an imbalance. Apart from the work of these two writers a certain amount of independent evidence has been collected which supports Wenger's hypothesis and the relationship between autonomic imbalance and neuroticism. Granger, in his section of this HANDBOOK deals with some of this evidence, as does Martin (Chapter 11) in hers.

If a decrease in neuroticism follows psychosurgery, then we might reasonably expect evidence of a decrease in the level of autonomic activity.

The evidence collected to date is entirely equivocal. Reitman (1945) summarized the effects of Proigine, eserine, ephedrine and Benzedrine on a group of fifteen leucotomized schizophrenic patients and an equal number of controls. Reitman characterized the drug effects as suggesting that the operations resulted in a tendency to maintain autonomic equilibrium, a conclusion indicating that a decrease in neuroticism may have occurred in this group. Rinkel *et al.* (1947a, 1947b; and in Greenblatt *et al.*, 1950) similarly reported that, although there was an initial heightening of autonomic responses after psychosurgery in their patients, equilibrium was re-established through readjustments within the autonomic nervous system over the passage of time.

The study of Elithorn *et al.* (1954) contains contradictory evidence on the question of the direction of the change, in the functions of the autonomic nervous systems after psychosurgery. On the one hand they found that their patients (twelve subjected to standard lobotomies, the others to more circumscribed operations) showed both higher surface skin temperatures and higher skin resistances and on the other, that a group of anxious patients showed reduced P.G.R. responses to a loud noise stimulus after the operation.

Ashby and Bassett (1950), however, had found the opposite results when they had compared the P.G.R. responses of a group of leucotomized psychiatric

patients to those of a control group. These authors concluded that there was no evidence of diminished emotional lability in the operated patients as shown by their P.G.R. records.

Chapman *et al.* (1950) reported a highly significant decrease in the tolerance of a group of post-psychosurgery patients for superficial pain (using the Hardy-Wolff Thermo-stimulator). Buck *et al.* reported a rapid reversion to a high rectal temperature after psychosurgery in a group of psychiatric patients who had shown this characteristic pre-operatively.

Finally, Malmo and Shagass (1950) have reported an extensive study of the effects of psychosurgery on the physiological correlates of anxiety. It should be noted that the psychiatric syndrome characterizing the patients of these authors would be held to be compounded of both introversion and of neuroticism. Malmo and Shagass proceeded from the hypothesis of Malmo (1942, 1948) (mentioned before in a different form), that the effect of psychosurgery is to reduce the capacity to maintain a set towards a goal, or to maintain an attitude of expectancy. They argued that anxiety is just such an attitude of expectancy and that psychosurgery would thus be effective when the capacity of the patient to maintain the expected attitude of anxiety was reduced.

Now, it has been argued that anxiety is a conditioned response—a conditioned fear response in fact—(cf. Chapter 13 by H. Gwynne Jones) and since we have described the extravert as being characterized by a resistance to conditioning processes and by a rapid extinction of established conditioned responses, a finding that post-psychosurgery patients were so characterized would be consistent with the contention that the post-operative change is one of increased extraversion. Describing anxiety as an attitude of expectancy, as Malmo and Shagass do, is, of course, tantamount to describing it as a conditioned response tendency, in the sense that this term is applied to human subjects.

Malmo and Shagass measured their subjects' capacity to maintain sets of expectancy in terms of the "potency of change in exteroceptive stimulation relative to the strength of internally maintained stimulation from sets and expectancies." They proceeded to test this notion by comparing the effectiveness of instructions in overcoming natural responses to painful stimuli in a group of thirteen post-operation cases and a like number of matched controls. Their subjects were instructed to keep their heads still while a heat stimulus was applied (Hardy-Wolff Thermo-stimulator). Measurements were taken on head movements, finger movements, respiration, P.G.R., heart rate and of muscle potentials from the head and neck.

In general Malmo and Shagass concluded that

exteroceptive stimuli showed increased potency in overcoming expectancies in their group. Moreover, they educed decreased amount of finger movement and decreased level of muscle potentials from the head and neck as further indications of a reduction in anxiety. It is significant that with the reductions in these analogues of "conditioned" responses of anxiety, there was an increase in the level of P.G.R., suggesting, if anything, an increased emotional response to the stimuli themselves.

Malmo and Shagass's work lends further support to the hypothesis we have proposed, but that the matter is a complex one is underlined by the findings of Sainsbury (1954). Sainsbury compared the autistic and communicative gestures of a group of leucotomized patients, a normal control group and a non-operated anxious group of psychiatric patients in an electromyographic study. He found that, pre-operatively, the patients made more autistic gestures than the group of normal controls and that post-operatively autistic gestures—those characterizing the mentally ill—were more decreased than the communicative gestures. He also reported that high pre-operative levels of anxiety, tension, depression and restlessness were associated with post-operative decreases in autistic movements. The implication that anxiety and tension were relieved by the operations we would have expected; that a decrease in autistic movement itself should have occurred suggests that factors other than extraversion were affected although the identification of what these factors were is not easy.

A number of studies on the rate of critical flicker fusion in psychosurgery patients have been made and are relevant to our discussion. It should be noted, first of all, that a large number of studies have associated low flicker fusion frequencies with extraversion. One can cite the studies of Madlung (1935), Washburn *et al.* (1930), Krugman (1947), Simonson and Brozek (1952) and Goldstone (1955). A close identification of what these authors have called extraversion and that factor we are referring to cannot

be made of course, since the same measure of introversion-extraversion has not been used in every case. Nevertheless, these findings are suggestive.

Halstead (1947b) compared the C.F.F. rates of twenty-five post-leucotomy patients with those of twenty-one neurosurgical cases from whom had been removed equal amounts of tissue from other areas of the brain and with those of a group of thirty normal controls. He reported that the post-leucotomy patients had significantly lower C.F.F. rates than either the normal group or the operated controls. Jones (1952) made daily determinations of C.F.F. rates for twenty days before and twenty-five days after leucotomy operations in a group of psychiatric patients and reported a significant drop in these rates after the operation. Landis and Clausen (1955) in a general study of sensory and motor performances following psychosurgery also reported a significant drop in C.F.F. rates for their post-operative group.

Such findings have not been unanimous however. Young (in Mettler, 1949) and King and Clausen (in Mettler, 1952) found only irregular and temporary lowering of C.F.F. rates in their post-operative groups and were unable to point to any consistent trends.

Summary and Conclusions from Molar Autonomic Studies

(a) A number of changes in autonomic functions are suggested in the literature although there are no conclusive findings. Those most commonly reported are: changes in P.G.R., temperature regulation, response to pain stimuli, C.F.F. rates and autistic movements.

(b) There is no conclusive evidence that those measures like P.G.R. which reflect emotional lability are lower after psychosurgery.

(c) There is considerable, although also inconclusive, evidence that measures either believed to be associated with extraversion or with the predominance of the cortical inhibitory potential are altered towards suggesting an increase in both after psychosurgery.

FINAL COMMENTS AND CONCLUSIONS

In the preceding review we have attempted to give a representative cross-section of the experimental work which has been carried out on the effects of psychosurgery. We prefaced our account with a brief summary of the clinical studies and included in it comparative investigations which seemed to be of direct interest and relevance. Without too grossly slanting our choice of studies for review towards its verification or refutation we have examined the hypothesis that an increase in extraversion is the

typical alteration in personality after psychosurgical procedures.

Summaries and conclusions have been given at the end of each section throughout the review and there seems little point in repeating them here *in extenso*, but, before concluding, we would like to offer these final comments and general summary—

(a) Psychosurgery has been based upon a set of observations of dubious validity and on a tenuous rationale.

(b) The most responsible and best executed studies in the field have been most cautious in associating specific surgical procedures with clinical improvements.

(c) Bearing the above caution in mind, the empirical evidence from the clinical studies points most regularly to psychoneurotic states of anxiety, tension and reactive depression being those relieved by psychosurgical procedures.

(d) When examined in terms of established dimensions of personality, the evidence, from the clinical studies, from the observations of animals, from the application of objective tests associated with these dimensions, and from the studies of molar autonomic changes, is almost entirely equivocal with respect to whether the operations reduce disease tendencies—here termed neuroticism and psychoticism—but strongly suggests that a change in the factor of temperament introversion-extraversion, towards a reduction of introversion, is the change most commonly observed.

(e) The systematic study of whether this hypothesis is a satisfactory one has not as yet been made, although the work of Petrie (1952; Le Beau, 1953, 1956) has laid necessary and substantial foundations for it. The methodology of such a study would require the testing of a homogeneous group of leucotomy patients of well-preserved personalities in a number of controlled laboratory experimental situations yielding measures of known relationship to the factors of temperament in question.

(f) Whether any purely cognitive deficits follow psychosurgical procedures also awaits systematic investigation but the available evidence from both the studies of human psychiatric patients and from comparative sources suggests that only relatively gross damage to the frontal lobes results in any deficit and even this evidence is far from conclusive.

This last comment highlights an issue which we have largely avoided—the site of the action of the operative procedures. At certain points in our discussion we have suggested that the truth of this matter may not be that superficially implied by the simple introduction of lesions into the white matter of the frontal lobes. In general we have simply attempted to relate operations to behavioural *sequelae* without concerning ourselves with the intervening processes. To have done so would have led us too far from our main purpose and field of expertise, but the issue involved here should be pointed out.

That the frontal lobes may not be as intimately concerned with higher mental processes, as has been long held, is an idea which has been filtering down from the laboratories of the neuroanatomists and neuropathologists for some time now. Fulton (1951)

has suggested that the site of action for psychosurgical procedures is in subcortical systems affected by degenerative processes and this and similar ideas have received considerable attention in the laboratories of comparative psychologists and physiologists (e.g. Chow and Hutt, 1953; Chow, 1954; French *et al.*, 1955; Peters *et al.*, 1956; Jameson *et al.*, 1957). The more technical evidence from neurology and physiology for what Penfield has called a “supracortical integrating mechanism,” identified with the reticular formation, is to be found in the symposium edited by Delafresnaye (1954).

In conclusion we must also point out that the interests of psychiatrists appear, at the moment, to be turning away from psychosurgery as a treatment for their patients, and this in itself strongly suggests the inadequacies of the technique. Instead, emphasis is being placed increasingly upon pharmacological therapies. The claims of the proponents of these often seem hardly more temperate than were those of the early proponents of psychosurgery. The possibility of descriptive and systematic investigations of the effects of drugs is great and presents almost none of the mechanical difficulties, inseparable from the investigation of psychosurgery—the provision of adequate control groups has been always difficult, for example. The efforts of clinicians and psychologists investigating the effects of psychosurgery have often been repetitious and wasteful. One can only hope that those concerned with describing the behavioural effects of the many drugs now coming into psychiatric usage will profit by this example.

CHAPTER 16

The Psychological Effects of Cerebral Electroshock

DUGAL CAMPBELL

INTRODUCTION

ELECTRIC convulsive therapy (E.C.T.) was introduced into modern psychiatry by Cerletti and Bini in 1938 (Cerletti and Bini, 1938). Electrically induced convulsions had been used before 1938 to treat mental illness (Sargant, 1957) but they had never been generally adopted as a standard form of treatment. Since 1938 E.C.T. has become a major therapy in psychiatry. One of the principal arguments in support of the claim that psychiatry now has effective methods of treatment turns upon the results claimed for E.C.T.

The use of convulsions was initially suggested by the supposedly low incidence of schizophrenia among epileptics. Metrazol therapy was introduced by Meduna (1935) on this basis and E.C.T. was at first regarded as a more convenient way of producing convulsions. For this reason a number of the earlier reports in the psychiatric literature of the results of E.C.T. are concerned with a comparison of Metrazol therapy and E.C.T. in cases of schizophrenia. Later, one finds papers which compare the effects of various forms of E.C.T. and assess the advantages of modifying the fit by drugs. E.C.T. has rarely been examined in its own right, perhaps because it has never appeared as a wholly novel treatment which has to be proved as better than existing treatments, or than no treatment at all.

As seems to be the case for many psychiatric therapies, an initial enthusiasm for E.C.T. has now been replaced by a more moderate assessment of the efficacy of treatment. Electroconvulsions are now thought to give the most satisfactory results in the treatment of cases in which depression is either the principal feature or among the major symptoms. Slater wrote in 1946: "Convulsion therapy has an almost specific remedial effect in one circumscribed psychiatric syndrome but as generally used in psychiatry it is a symptomatic method for the treatment of depression." The syndrome for which E.C.T. is thought to be particularly effective is involutional

melancholia. Claims have been made for recovery in up to 90 per cent of these cases (Slater, 1946).

The supposed antagonism between schizophrenic processes and physical convulsions is now thought to be unlikely as schizophrenia appears to be neither opposed to nor associated with epilepsy (Hoch, 1943). But the success of E.C.T. in alleviating depression has led to renewed speculation concerning the *modus operandi* of E.C.T. Some believe, for example, that the shock activates the autonomic nervous system to restore normal function. Others hold that the shock acts as it does because it causes damage to the brain. And it has been proposed that E.C.T. acts as a "punishment" which satisfies a patient's psychodynamic needs. None of these, or any other view, has yet been adequately demonstrated. So it may be said that E.C.T. is an entirely empirical treatment at the moment.

Given such a situation there appear to be at least four overlapping tasks which may suggest themselves to psychologists. In the first place, psychological methods may be used to estimate the efficacy of the treatment in alleviating depression and in returning patients to ordinary life. In the second, research may be concerned with the effects of E.C.T. upon measures of specific psychological functions, for example memory or intelligence. In the third place, psychological research may be of assistance in examining hypotheses concerning the mode of action of E.C.T. One might examine, for example, the notion that memories with painful associations are particularly influenced by E.C.T. And lastly, the construction of test batteries to predict the outcome of E.C.T. suggests itself as a line of investigation.

Ideally these four tasks should form part of an expanding and coherent body of knowledge. If such were the case both the prognosis in any particular instance and general psychological effects might be derived from a rational account of the action of E.C.T. and the division of the topic into four aspects would

appear to be artificial. This ideal is not yet realized. The four divisions seem a reasonable way of viewing E.C.T. and may assist in assessing psychological research in this area.

In fact, psychological studies have not, for the most part, been, by design, directed at these aims, and it is more convenient in the first instance to describe the experiments by making a main division into animal and human studies. Animal subjects have been used by a number of experimenters as they make possible experimental designs which could not be applied to human subjects. In this connexion one may note that Cerletti applied electric current to his first patient only at the end of a series of experiments upon animals which culminated in his observation of the use of electricity in making pigs insensible in the Roman *abattoirs*. The majority of these experiments have been directed at describing the effects of E.C.T. upon psychological function although a few have examined aspects of explanations of E.C.T.

Other experimenters have used E.C.T. as it is ordinarily given in hospitals as an experimental variable, accepting the limitations which are thus necessarily imposed upon research design. Many experiments of this type of research, have failed to include control, or untreated, groups and consequently the results cannot be attributed unequivocally to E.C.T. None of these experiments is a direct attempt to measure the efficacy of E.C.T. The aim of the majority is to report upon the psychological effects

of E.C.T., and a few examine explanations of E.C.T.

An idea of current psychological interest in shock treatment is given by the citations in *Psychological Abstracts* for 1956. Thirty-six refer to electroconvulsive shocks but only three of these report on changes in psychological measures in human subjects. Six refer to animal subjects and the remainder treat the subject either from a psychiatric or from a physiological point of view.

At the moment there can be no doubt that the researches upon animal subjects provide information which is more reliable than do those which used human subjects. But, though many of the animal experiments use E.C.T. as a pattern it remains uncertain how the results may be applied in explaining the effects of E.C.T. in humans. Generally the experimenters who used animal subjects have been cautious in interpretation. One has said: "The greatest chances for success in discovering the secrets of the electroconvulsive shock mechanism lie in capitalizing on the advantages of research using both human and infra-human subjects." (Russell, 1948.)

The present status of work on E.C.T. is reviewed in this paper in the light of the animal experimentation as this comparison gives a clear idea of the value which can be assigned to the work with humans. The comparative psychologist has admitted advantages in experimental design but, even allowing for this, the comparison is not flattering to clinical psychology.

EXPERIMENTS USING ANIMAL SUBJECTS

Finger (1947) surveyed the several ways of inducing convulsions in rats and the various means of lowering convulsive thresholds. In common with other papers written at that time the discussion is influenced by Maier's experiments from which it appeared that convulsions could be induced by subjecting the animals to a series of insoluble trials in a Lashley jumping stand. It appeared from Finger's review that convulsions, which were behaviourally alike, had been produced by a variety of agencies, including electroshock, and that these convulsions had effects upon habits for at least some time after the convulsion. Golub and Morgan (1945), Siegel and Lacy (1946) and Stainbrook (1946) reported that electroshock produced full grand mal convulsions in the absence of any other form of stress. The course of the convulsion was described in detail by Golub and Morgan and has been consistently observed since in experiments of this type.

It therefore appeared that occurrence of convulsions could be treated as an independent variable in psychological experiments rather than merely as an effect of

some other psychological variable, such as frustration. Stainbrook made the point that the convulsion follows the electrical stimulation directly in some cases and therefore "the abnormal behaviour pattern may occur in the absence of any psychologically significant state of fear," due to pain from the passage of current.

Shock Variables and Subject Variables

When E.C.T. in human subjects and electroshock convulsions (E.S.C.) in animals were first examined attention was given to the type of electric current used. It was found that alterations in the physical characteristics of the current produced differences in the onset of the convulsion. It has been noted that rectangular current has a lower threshold than ordinary alternating current in producing shocks (Merritt and Putnam, 1938) and that such threshold differences are sensitive to slight changes in current intensity (Pierce, Russell and Patton, 1950). In individual animals the threshold for a given current is constant from day to day.

The direct physical consequences of E.S.C. also

vary with the current used. As the intensity and duration of the current used become greater, more cases of paralysis due to fractures and dislocation of vertebrae are found (Russell, Townsend, Braun and Patton, 1948).

But it is not certain how variation in current is related to subsequent psychological changes. Hayes (1948) examined the behaviour of rats in a three-choice-point T maze after petit mal convulsions and after grand mal convulsions induced by currents of either 35 milliamperes or 150 milliamperes. The results of the 35-mA and 150-mA groups were indistinguishable. From this it appears probable that the convulsion is an "all-or-nothing" reaction which proceeds independently of the stimulus once the threshold is reached. Townsend, Russell and Patton (1949) obtained similar results when they compared groups of rats given shocks of 25, 30 and 35 mA.

However Docter (1957) used square-wave d.c. current to evoke convulsions (brief stimulus therapy) and found that this had a less disruptive effect upon behaviour than 60-cycle a.c. current. This result is in agreement with those from human subjects in which the side-effects of E.C.T. are said to be avoided by using "brief stimulus therapy."

The number of shocks included in a series is related to subsequent impairment. The form of the relationship is not known but larger numbers of shocks produce greater changes (Brown and Wilbanks, 1952; McDonald and Stern, 1956).

The experiments upon shock variables have led to the use of apparatus, such as the Pittsburgh apparatus, which enables the experimenter to control the characteristics of the current, even though the load may vary. A typical shock used in experimentation with rats will have characteristics of this order: 50 mA of 60-cycle a.c., delivered for 0.2 sec through alligator clips attached to the subject's ears.

Some subject variables have also been investigated. As the weight of a rat increases the threshold for shock increases. If weight is held constant an increase in age causes a drop in threshold (Pierce and Patton, 1952). Two strain differences have been examined. No differences were found between albino and black hooded rats (Bendig and Braun, 1951), though the authors point out that finding no differences in one comparison does not imply that all genetic variables may be discounted. A comparison of tame and feral rats was made by Stone (1953). He found that feral rats showed a different shock pattern from that found in tame rats. Within the group of feral rats a non-shock group showed a decline in wild behaviour whereas a shock-group showed no change at all in emotional response during a series of shocks and remained wild despite frequent handling.

General Effects of Electroshock Convulsions

A complication which arises in assessing the results of E.S.C. in animals is that decrements in performance on a particular task may be due to some general effect of E.S.C., such as an alteration of drive, rather than being due to a specific action of E.S.C. upon the functions in question. In a number of experiments such general changes have been noted.

Page (1941) attempted unsuccessfully to condition E.S.C. He noted that repeated convulsions led to loss of weight, inactivity and passivity in his subjects. Similar results have been reported by Stone (1946) and Winder (1946). A reduction in voluntary activity occurred within twenty-four hours after shock in each case. Once the shock series had ended activity returned to the normal level again or even surpassed it.

Stern (1956) used the open field test to show changes in emotionality after E.S.C. A series of fifteen E.S.C. produced a decrease in activity and an increase in emotional behaviour which lasted for as long as one hundred days after the last shock. The disagreement of other authors on the degree and sort of emotion shown by their subjects is attributed by Stern to the varied situations in which they made their observations.

Mirsky and Rosvold (1953) suspected that activity changes might indicate loss of drive. They found that shocked rats on an *ad libitum* food schedule reduced their food intake, but that groups of rats on a deprivation schedule showed increased motivation as measured by bar-pressing to obtain food and subsequent *ad libitum* feeding. Stern (1954) had rather similar findings: an *ad libitum* feeding schedule caused shocked animals to lose weight whereas a twenty-three-hour deprivation group showed no change. Jensen and Stainbrook (1949) found a weight gain in an E.S.C. group.

Mirsky and Rosvold point out that the hunger drive and the influence of E.S.C. may cancel out in such a way that increased motivation due to deprivation may equal a drive decrement due to E.S.C. They adduce conflicting evidence from other experiments (McGinnies, 1947; Bernberg, 1951) to support this. They emphasize that the feeding schedule of animals should be specified in experiments and that the drive states of the shocked and non-shocked groups must be comparable.

In a later study, however, (Mirsky, Looney and Rosvold, 1954), no differences were found after E.S.C. in a maze habit between groups of rats, one maintained at 85 per cent of initial weight and another allowed to make a steady weight gain. It consequently appears that the variations in the results from other studies may not be attributed unequivocally to variations in hunger drive.

A number of experimenters have observed changes in specific functions or behaviours which seem to

imply that E.S.C. produce quite profound changes in a variety of physical systems. These, in turn, may underlie the specific effects which are expected in maze and runway performance. The disturbance of the oestrus cycle noted by Jensen and Stainbrook (1949) is doubtful in view of Nolan's (1952) negative report. But marked disturbances of the gestatory process and subsequent maternal behaviour are produced by E.S.C. (Bacon and Rosvold, 1948; Rosvold, 1949). The disturbances in both gestation and maternal behaviour were less marked when the shocks were given later in the gestation period. Maternal behaviour was less disrupted when the shocks were not given immediately following the birth of the pups. These changes are especially interesting as other experiments have shown that maternal behaviour is largely governed, in ordinary circumstances, by the internal secretion of hormones, and by cortical centres. The prolongation of pregnancy and increased difficulty in labour are attributed to dysfunctions of the endocrine system. Rosvold notes that there are marked individual differences in the resistance of mothers to the effects of E.S.C. The number of shocks given is related to the alteration of function; one shock given twelve hours after copulation had no effect whereas six and eleven shocks given on successive days had increasing effects so that, in the eleven-shock group, the foetus was entirely resorbed (Bacon and Rosvold, 1948). Bauer (1955) also reported that E.S.C. disrupted nest-building activity.

Beach, Goldstein and Jacoby (1955) examined the effect of E.S.C. upon sexual behaviour in male rats. Various measures of sexual activity were taken before, during and after E.S.C. It was found that the subjects became less responsive to stimuli which normally set off the initiation of copulation but became more responsive to stimulation derived from the act itself; the increased reactivity to coital stimulation is retained for up to twenty-eight days. These results are explained by Gellhorn's hypothesis of shift in autonomic activity toward the sympathetic system (Gellhorn, 1953), and the additional assumption that E.S.C. temporarily reduces parasympathetic activity.

Other changes in levels of physiological function have been found. MacMahon (1929) found that electric shock caused marked and sudden pressure changes in the cardiac system. Hoyt and Rosvold (1951) showed that normal variations in rectal temperature are reduced by E.S.C.

These results indicate that E.S.C. acts not only upon individual habits but generally upon the physiological bases of behaviour. In consequence, in any particular instance one must be cautious in attributing alterations in a particular behaviour directly to the action of E.S.C. as they may be due to

changes in a general physiological system. The way in which these changes are brought about is still obscure.

Retention of Habits after E.S.C.

The use of E.C.T. led to noticeable amnesias in patients immediately after the shock which, apparently, cleared up in a matter of hours. This observation naturally led to experiments concerning the retention of previously acquired habits after E.S.C.

Among the simplest responses examined have been conditioned responses. It was found that, when a conditioned response had been extinguished by a series of non-reinforced trials, the use of electroshock led to a reappearance of the initial conditioned response. (Gellhorn, Kessler and Minatoya, 1942; Gellhorn and Kessler, 1943; Gellhorn, 1945). These results suggested that E.S.C. may act specifically upon inhibited conditioned responses. Rosen and Gantt (1943) using Metrazol found that convulsions led to loss of discrimination in a conditioned response, which was made to both negative and positive stimuli. This, too, may be attributed to an alteration in inhibitory processes.

The bulk of research on habit retention after E.S.C. has used the straight runway or maze learning as a means of showing decrement in performance. Both were used to measure the consequences of audiogenic seizures, and to compare the results of audiogenic seizures and E.S.C. Stainbrook and Lowenbach (1942) reported that both "noise-fright" reactions and E.S.C. led to disorientation in rats so that they required much longer to run mazes though the error scores were unaltered. McGinnies (1947) also found great changes in maze time scores but none in error scores after E.S.C. Because of the larger variance in the results of his shocked group he suggested that individual differences in the ability to withstand stress rather than any direct neural effect might underlie the post-shock performance. Shaw, Utecht and Fullager (1953) found similar results after audiogenic seizures. They attributed the greater time scores to the time the animals spent in hiding on the way to their food-box and suggested that fear may lead to this response at the expense of goal seeking. Such results bring out the difficulties mentioned in the previous section. The increase in time scores is consonant with greater inactivity but it is uncertain, in these cases, whether or not some emotional state accounts for the changed behaviour.

A number of experiments have investigated the effects of E.S.C. upon tasks of varying difficulty. When very simple tasks of the maze variety are used it becomes more difficult to detect post-E.S.C. changes in performance. Siegel (1943) found no change in the overall speed of running through a

runway. In a second experiment which measured component parts of the runway behaviour (Siegel and Siegel, 1949) E.S.C. was found to abolish the anticipatory goal reaction. In the second experiment, moreover, a control group of animals was shocked in the leg as a means of controlling for emotional change. Shock to the leg does not have the effect of E.S.C. in abolishing the anticipatory gradient.

Behaviour on more difficult tasks can more readily be shown to be influenced by E.S.C. Duncan (1945) used a Lashley type-III maze in an experiment which included an E.S.C. group, a leg-shock control group and a no-shock control group. On a relearning trial after shock the experimental shock group was significantly inferior to the controls in error scores, time scores and in the number of trials necessary to re-achieve mastery. He concluded that the effect of E.S.C. is specific to the central nervous system as shock to the legs had no effect and therefore fear might be excluded as a cause of habit decrement. Townsend, Russell and Patton (1949) showed decrements in retention of a Lashley III water-maze immediately after E.S.C. On a task at the extreme edge of the animal's capability the effect of E.S.C. may be to make it impossible for some rats to relearn the task and all have great difficulty. This has been reported for a double-alternation task (McGinnies and Schlosberg, 1945; Palmer, 1950). Cats, on the other hand, show no post-shock decrement in double-alternation problems.

Russell (1949) used a five-choice-point maze in conditions identical with those of earlier experiments. He was able to show a clear interrelationship of retention and task difficulty. The more difficult the task the less it is retained through shock.

Another feature of the effects of E.S.C. suggested by observations of human patients and the conditioned response experiments was that the effect might be greatest in the case of more recently acquired habits. Duncan (1948) trained rats first to go left in a T-maze and then to go right. The intervention of a single shock caused a significant revival of the earlier left-going habit though not all his subjects exhibited this. He pointed out the possibility that the therapeutic effect of E.C.T. may depend upon the removal of recently acquired habits which permits older ones to reappear. Braun and Patton (1950) demonstrated a limitation to this conclusion. If two tasks are of equal difficulty an earlier learned task will tend to reappear after E.S.C. and will be persisted in. But if the two tasks are of unequal difficulty then the earlier learned of the two responses will reappear only when it is also the simpler of the two.

As more recently acquired habits are often also "younger" habits in terms of the time and trials elapsed since acquisition, attention was turned to the

effects of E.S.C. upon habits acquired at various time intervals before the shock series. Duncan (1949) trained rats to avoid a charged grid and gave them shocks at varying intervals after each trial; the intervals varied from twenty seconds to fourteen hours. He also used a leg-shock control group. The effect became progressively less so that animals shocked at one to fourteen hours after each trial showed no significant difference in the amount of learning impairment from the leg-shock or unshocked controls.

Worchel and Gentry (1950) compared the effects of E.S.C. given either immediately after criterion learning or four hours later. When a retest was made twenty-four hours later the immediate shock group showed the greater decrement. Worchel and Narciso (1950) repeated the experiment but included a retest four days later rather than twenty-four hours later. In these conditions the immediate shock group showed no impairment and was indistinguishable from a no-shock group. The changes caused by immediate shock appear to be temporary; in this instance six E.C.S. had been given. Thompson and Dean (1955) examined the effect on a discrimination habit of shocks given at ten seconds, two minutes, one hour and four hours after the last criterion trial. In this case, at retest forty-eight hours later, the groups with the shorter criterion-trial shock intervals showed the greater decrement.

These results are generally interpreted in terms of a neural reverberation or consolidation theory. This process is thought to be essential to retention and is disrupted, particularly in its early stages, by E.S.C.

Another line of evidence which may be related to this process is provided by experiments which investigated the relations between degree of learning and the amount of retention after electroshock. Over-learning considerably reduces the effect of E.S.C. (Worchel and Gentry, 1950; Braun and Albee, 1952). Braun and Albee compared the effects of 200 per cent and 600 per cent over-learning. The 600 per cent over-learning group did not differ significantly from the no-shock control group, and, in terms of saving scores, the 200 per cent over-learning group was also shown to be effective in resisting the consequences of E.S.C.

The effects of E.S.C. appear to lead to a permanent decrement in retention if a sufficient number of shocks are given. Worchel and Gentry found no decrement on retest four days after six shocks. But, after twenty-five convulsions, Russell and Patton (1949*a*; 1949*b*) showed larger trial, error and time scores on a water-maze in a convulsed group at one, thirty, sixty and ninety days after the last convulsion. Though an improvement in absolute performance level took place there was no reduction in degree of relative impairment shown by the shocked groups at each trial.

E.S.C. and Learning

The notion that E.C.T. may have permanent ill-effects in humans is paralleled in animal research by the idea that learning may be permanently impaired. Stainbrook (1943) trained rats in a two-choice-point T maze, gave them a course of E.S.C. and examined relearning in the maze. The shocked group took longer to relearn the mazes and made more errors than the control group. But, compared with their original learning curves, the time scores of the shocked group were better and the error scores were the same. In many studies of this type a "learning impairment" is discussed in terms of the discrepancy between the performances of a shocked experimental group and a non-shocked control group during relearning trials, following the pattern of the retention experiments. In these cases the "learning impairment" may in fact be a performance decrement due to E.S.C. which necessarily causes a longer relearning process as the shocked group begins relearning at a lower level of performance. The most informative comparison for this purpose would appear to be between relearning after shock and the original learning at the same level of proficiency.

Hayes (1948) examined this point. He found in a group of rats given grand mal shocks significantly poorer relearning curves in a three-unit T maze for both time and errors in cases where the initial relearning score happened to be very much the same as in the control group. Muhlan and Stone (1949) used a Dashiell-type water maze. They noted that, compared with a control group, a shocked group showed a weaker tendency to adopt the most economical route through the maze, covered greater distances and made more "reversals" of direction with respect to the goal. In the shocked group the evolution of an economical central path began only when the shock series ended. In a later problem, however, the convulsed group showed no certain handicap in habit formation. Rishikoff and Rosvold (1953) found impaired learning in rats on the Hebb-Williams closed field test which, they remark, provides a better analogy to human intelligence than maze problems. They found poorer initial learning thirty-five days after a series of fifteen shocks, shown by greater error scores in the shocked group. Bendig and Patton (1952) found that E.S.C. reduced latent learning.

An experiment by Horowitz and Stone (1946) is interesting as it contrasts the disorganization of a recent habit by E.S.C. and reduction in learning. They reversed a discrimination habit in shocked rats expecting that the disorganization of the previous habit by E.S.C. would facilitate learning of the new habit. In fact, the opposite result was found. The original habit was indeed disorganized after shock

but a non-shock group learned the reversed habit more readily than did the shocked group.

Rather similar results were obtained from monkeys. A "learning set" training was ended by giving a series of E.S.C. On retest for retention of the learning set, control animals had a higher rate of correct responding than the experimental animals which made only a slow approach to the level of the controls. The inferior performance of the shocked group in this case was due to a tendency to make perseverative position responses (Braun, Patton and Barnes, 1952). However, further tests of delayed responses and oddity problems given twenty-four and ninety-four days after E.S.C. showed no decrement and suggested that the previous results represented a temporary change (Braun, 1952a; 1952b).

Eriksen, Porter and Stone (1948) examined the possibility that E.S.C. produces irreversible impairment in learning ability if given in infancy. They used a split-litter technique and a multiple T-maze. They found, in rats shocked daily from twenty to twenty-nine days of age, slightly more errors and trials before mastery was attained in a T-maze than in a non-shock group. These results were found at ten, twenty and up to ninety days after the last shock. In a combined analysis of these results no decline in relative impairment could be related to the test-retest interval so it appeared that E.S.C. in infancy leads to a permanent decrement in ability which remains constant (Porter, Stone and Eriksen, 1948). Similar results were found by Braun, Pierce and Patton (1950) and Bernberg (1951). In every case the experimenters noted that the differences in actual performance were small and stiff criteria were necessary in order to demonstrate the effect. These results have been attributed to irreversible brain damage.

A contrary result is reported by Rishikoff and Rosvold (1953) on the Hebb-Williams closed field test. The shocks were given for ten days to rats aged twenty to twenty-nine days but led to no apparent increase in errors during training at one hundred and fourteen days of age.

The Effects of E.S.C. upon Emotional Responses

As the principal effect of E.C.T. is upon mood it is naturally of interest to investigate change of mood in animals. However in order to do so some marked emotion must be set up in animals and some way of measuring subsequent changes in the emotion must be found. "Anxiety" as defined by Estes and Skinner (1941) has been used in a series of experiments which have outlined the course of this response after E.S.C. Provided no alteration is made in experimental arrangements the anxiety or "conditioned emotional response" is very slow to extinguish, and shows nearly complete spontaneous recovery after extinction.

This stability of response was used to provide a useful indication of the effect of E.S.C.

Hunt and Brady (1951) used the cessation of bar-pressing in a Skinner Box as an index of "anxiety" in response to a sound which had previously been paired with an electric shock to the paws. After a course of E.S.C. the shocked animals continued to press the bar when the sound signal was presented whereas a non-shock control group retested at the same time continued to show the acquired anxiety response. In the shocking-box itself the experimental animals showed a return of exploratory behaviour whereas non-shock control animals crouched and defaecated. In a series of control experiments this result was confirmed and the possibility that it was due either to impaired hearing or to competition between the two responses of bar-pressing and crouching was excluded (Brady and Hunt, 1951; 1952). In subsequent reconditioning trials the experimental animals were all able to acquire the emotional response again. In later experiments bar-pressing was again used because of its advantages as a readily quantifiable index of anxiety. Anxiety means, in this context, a decline in rate of bar-pressing immediately following presentation of a signal which has been paired with a painful stimulus.

Brady (1951) examined the effect of E.S.C. upon the conditioned emotional response at thirty, sixty and ninety days after completion of the shock series. Four days after the shock series the emotional response had disappeared as it had done in the previous experiments. At thirty, sixty and ninety days, however, it reappeared and the effect of E.S.C. could only be detected in the smaller number of trials which the shocked group required for extinction to take place. A plausible suggestion in the light of these results was that, as time passed, the emotional response became stronger. This possibility was examined by giving E.S.C. at intervals of thirty, sixty and ninety days after the emotional conditioning and then examining for retention of the emotional response four days after the shock series. In this instance the emotional response was not abolished by the E.S.C. Only during extinction trials could the shocked animals be distinguished from the controls. But even this difference between the groups decreased as the period between emotional conditioning and the shock series grew longer. This goes to support the notion that conditioned emotional responses increase in strength as a function of elapsed time so as to offset the action of E.S.C. (Brady, 1952). Subsequently it was found that ordinary extinction procedures, applied immediately after the shock series, during the time in which the emotional response was temporarily abolished from the animals' behaviour, had the effect of permanently abolishing it. This confirms

the notion that during the post-shock period the emotional response still has covert representation of some kind in the central nervous system (Hunt, Jernberg and Brady, 1952). These results recall the clinical observation that depressions of long standing are more resistant to E.C.T.

Similar results are obtained with audiogenic seizures which also abolish conditioned emotional responses (Brady, Stebbins and Galambos, 1953). An interesting additional fact was that the rank-order correlation between the number of seizures and the alteration in the rate of bar-pressing was 0.89. The "convulsive process" is assumed to be the event common to the two experimental procedures and, therefore, either it, or its effects, must be the cause of behavioural changes.

In the experiment of Brady, Stebbins and Galambos it emerged that the temporal distribution of convulsions was of importance in eliminating the emotional response. Convulsions on alternate days were not so effective as convulsions every day. This finding led to further investigation of this point. The experiments in the series initiated by Hunt and Brady had used a procedure in which the rats were given twenty-one shocks at the rate of three a day. Brady, Hunt and Geller (1954) gave twenty-one shocks at intervals ranging from one second to seventy-two hours. The emotional response was eliminated only in the groups which were shocked at intervals of one, eight and twenty-four hours, and was partially eliminated when the intervals were one-half, forty-eight and seventy-two hours. The animals given twenty-one electric shocks in twenty-one seconds had only one convulsion however, and in their case the retention of the emotional response is consistent with previous findings; similarly not all the animals shocked at half-hourly intervals had twenty-one convulsions. The partial elimination which occurred after convulsions at forty-eight and seventy-two hours suggests an interaction between the cumulative effects of E.S.C. and the gradual increase in the emotional response.

The possibility suggested by experiments in maze retention, that the emotional responses were eliminated solely because they were the most recently acquired responses was examined by Geller, Sidman and Brady (1955) who reversed the usual order of acquiring first, the bar-pressing response, and then the conditioned emotional response. In this case too the emotional response was eliminated by E.S.C.

Poschel (1957) examined both the retroactive effect, and the proactive effect of E.S.C. upon anxiety by using the approach-avoidance conflict in a runway. In his shocked groups E.S.C. acted both proactively and retroactively to reduce the fear component in the conflict. The novel element in this study is provided by the proactive effect of E.S.C. Poschel argues that

these results support the notion of some physiological change caused by E.S.C. which provides a temporary basis for altered emotional behaviour.

Avoidance responses have been investigated in a similar fashion. Heistad (1955) found the E.S.C. weakened a conditioned avoidance reaction to electric shock to the paws. Carson (1957) found similar results. Hamilton and Patton (1952) examined an extinguished avoidance reaction and found that it was reactivated by the intervention of E.S.C. though not all the subjects showed this recovery on all the trials.

E.S.C. and Maladaptive Responses

Masserman and Jacques (1947) examined the effect of E.S.C. upon experimental neuroses in cats. They found that after E.S.C. the shocked animals showed a change in behaviour. Phobias and compulsions disappeared and more adaptive behaviour emerged. This did not occur in all the animals examined but, if it occurred at all, the change continued for periods of up to ten weeks. This tendency could be further improved by guidance. Later in this experiment it was found that all of the neurotic subjects and two of the controls showed an impaired ability for complex adaptation. A second experiment, using "milder" shock, led to the reduction of both normal and neurotic behaviour. In this case all but one of the neurotic subjects failed to respond to guidance as a means of restoring adaptive behaviour (Masserman, Arief, Pechtel and Klehr, 1950). It is not entirely clear from these experiments which variable produces the alterations in behaviour: shock or subsequent guidance.

Neet and Feldman (1954) established a fixated jumping response in rats which was tested for stability during a twenty days' series of insoluble responses. They found that neither a ten-shock or a twenty-four-shock series caused the rats to abandon the fixated response. In a second experiment (Feldman and Neet, 1954) they combined shock and guidance. No significant differences were found between the shock and non-shock groups for the rate extinction of conflict-induced responses, or the number of animals able to solve the problem. In a later experiment (Feldman and Neet, 1957) they examined the possibility that their results were due to over-learning the fixated response during the many trials which permitted no consistent escape from punishment. It will be recalled that over-learning substantially reduces the effects of E.S.C. In this case too it was found that the conflict-induced fixations were not altered by E.S.C. Indeed there were consistent suggestions that E.S.C. delayed the breaking down of the stereotype; the non-shock control group learned quicker on retest.

E.S.C. and Drugs

In a number of cases E.S.C. have been given while the animal has been drugged. Porter and Stone (1947) found that E.S.C. given under ether anaesthesia produced less interference with maze learning than E.S.C. given in the ordinary way. Similarly ether anaesthesia at the time of the passage of current affords almost complete protection against the deleterious effects of E.S.C. upon gestation (Stone and Walker, 1949). Siegel, McGinnies and Box (1949) compared shock under surgical anaesthesia (Nembutal), shock and a *placebo* (saline injection), and the anaesthesia alone upon running time in a straightway. Both groups given the Nembutal were unimpaired on retest. The saline-shock group showed an increase in running time. It was concluded that anaesthesia protects the animal from the disturbing effects of E.S.C. The disturbances therefore seem to be dependent upon the convulsion and not upon the passage of the current as such. This result is analogous to the observations made of E.C.T. in human subjects, where a general anaesthesia has no apparent influence upon the beneficial changes but eliminates many of the physical risks.

The effects of E.S.C. upon emotional responses are also diminished if the convulsion is blocked by ether anaesthesia (Hunt, Jernberg and Brady, 1952).

Not all drugs have this effect. Epanutin does not modify the effects of E.S.C. upon maze performance (Broadhurst, Stone and Lawrence, 1952). Similarly E.S.C. under Epanutin or amphetamine does not prevent the usual attenuating effect of E.S.C. upon an emotional response. But E.S.C. under Phenurone does not have its usual effect upon an emotional response. These various results presumably reflect the different actions of the drugs (Hunt and Beckwith, 1956).

E.S.C. as a Cause of Brain Damage

Damage has been found in the brains of a number of animals following electric shock procedures. The most common type of damage has been haemorrhages in the meninges and within the brain (Morrison, Weeks and Cobb, 1923). The changes which occur apparently happen immediately and the evidence for them diminishes as the interval between shock and inspection increases (Heilbrunn and Liebert, 1941). The damage appeared as haemorrhages which were attributed to the sharp rise in arterial blood pressure during muscle contraction and vasospasm of peripheral arteries (Heilbrunn and Weil, 1942; Alpers and Hughes, 1942). There is additional evidence to support the view that changes in circulatory pressure during the convulsion, and not the current itself, cause the lesions because when the convulsion is

prevented by ether narcosis the haemorrhages no longer occur (Heilbrunn, 1943).

The changes that occur tend to be reversible, though they are longer lasting after more intense shocks and in the current path. Hartelius (1952) found both reversible and non-reversible changes in the brains of fifty-seven cats given E.S.C. Ferraro and Helfand (1946) suggest that these reversible changes may be the basis for alterations in the mental processes of patients. However Siekert, Williams and Windle (1950) found no differences in the brains of five shocked monkeys and one control. They claimed their technique excluded post-mortem change in the brains which could give rise to the results reported by other workers.

Hypertrophy of the rat's adrenal gland has been found by Rosvold, Kaplan and Stevenson (1952) after E.S.C., though similar shocks given under anaesthesia gave no such enlargement. The coincident changes in adrenal size and behaviour provide another possible basis for the effects of E.S.C. Royce and Rosvold (1953) give further detail of endocrine changes. They found that anticonvulsant drugs given alone led to adrenal enlargement. They therefore gave additional electroshocks to animals in which further convulsions were blocked by the tonic-extension phase of the convulsion which followed the previous electroshock. In this case the current alone led to endocrine system changes (Gellhorn, 1953).

Explanations of the Consequences of E.S.C.

The experimenters who carried out the work upon animals described in the preceding sections were often led to their particular topics by considering clinical reports of the effects of E.C.T. It is natural to ask if their results are relevant to E.C.T. and if they go any distance towards providing a model for E.C.T. By and large, if one accepts the analogy between E.S.C. and E.C.T., the results are in one sense encouraging and in another discouraging. In a general sense they are encouraging as they indicate how substantial a portion of inborn and acquired psychological function survives a course of electroshock convulsions. Moreover ways in which the effects of convulsions may be reduced are also indicated. A particularly striking feature is that many of the suggestions from clinical observation have led to animal experiments whose findings, in turn, suggest further lines of research in both animal and human subjects. But in detail the results are not in close agreement. It appears that E.S.C. can have an effect upon established habits, particularly those more recently acquired, and that these effects may be permanent in certain circumstances. On the other hand, changes of emotional response are not per-

manent and maladaptive habits cannot be altered more readily with the aid of E.S.C.

These conclusions run counter to clinical observations of the results of E.C.T., which is said to have no marked or permanent effect upon habits or cognitive functions, and may lead to effective permanent changes in mood and emotional tone.

Animal research has generated a number of explanations of the consequences of E.S.C. These explanations must also be thought of as candidates for the explanation of the effects of E.C.T. These explanations have turned upon either brain damage or a "consolidation" theory of neural function or Selye's general adaptation syndrome.

The brain-damage theory considers that the changes in behaviour turn upon reversible or irreversible brain changes. These have not been exactly specified but are assumed to become permanent if, either many shocks are given in a series or if they are given in infancy.

The consolidation theory supposes that E.S.C. act as they do because they break up an assumed "reverberation" or consolidation process which is necessary to the establishment of a habit. The results which support this view most completely are those which show how E.S.C. have less effect when an interval elapses between habit training and shock administration. Such reverberating circuits of the kind suggested have in fact been shown only between whole units of the central nervous system but they are assumed to exist on a local scale. Attempts have been made to provide evidence for the consolidation theory by slowing down the reverberations, so that a longer time is required to fix the habit, and then introducing E.S.C. which, if the theory is sound, should have disruptive effects as great as those generally found after shorter periods. One such attempt, which used cooling to slow the reverberatory process, showed disruption of a maze habit in hamsters after an interval of one hour as great as that ordinarily found with a training-shock interval of fifteen minutes (Gerard, 1955). Another experiment by Leukel (1957) in which Sodium pentothal was used to slow nervous activity produced results consistent with those of Gerard. A greater distribution of learning trials, which on this view should assist resistance to E.C.T., has the predicted effect (Thompson and Pennington, 1957).

The theories which evoke the general adaptation syndrome (Selye, 1950) emphasize the non-specific action of electroshock, and subsequent changes in the hormonal and central nervous systems. Riess (1948) has presented data on rats subjected to large numbers of shocks which he believes represent the three stages of the syndrome: alarm, resistance and exhaustion; in terms of maze performance the sequence was decrement, improvement and maladaptation. He also showed that dietary changes influenced the course of

performance in a predicted manner. This view has been put into psychological terms by Heistad (1955) who draws on the changes in the hypothalamus and autonomic nervous system found after E.C.S. by Gellhorn (1953), and the notion of stimulus generalization to account for changes in conditioned emotional response. He suggests that the internal stimuli due to autonomic activity are altered because the autonomic activity is itself changed by shock. One will obtain different responses in accordance with stimulus generalization, depending on how unlike the original stimuli are to the altered stimuli.

In each of these three explanations the theorists have had to lean heavily upon either physiological research or upon assumptions concerning physiological processes. It is doubtful if the data at present available concerning the physiological changes following E.S.C.

are sufficient to provide an adequate basis for definitive conclusions. The "explanations" are, properly speaking, research programmes. Beach's remark is still true: "... [The effects of E.S.C.] are so numerous and so widespread that much additional experimentation will be necessary before any reasonably satisfactory interpretation of the present findings can be anticipated." (Beach, Goldstein and Jacoby, 1955.)

The prediction made by Harlow (1956) that work on E.S.C. will be discontinued within ten years is likely to be borne out in the sense that the psychological consequences of E.S.C. will be clearly defined. But it appears that work upon the physiological bases of the psychological effects is just beginning and much more will be necessary if E.S.C. and E.C.T. are to be satisfactorily explained.

RESEARCH USING HUMAN SUBJECTS

The experiments upon animals which were described in the preceding sections provide not only a number of suggestions for the psychological effects which may be looked for as consequences of E.C.T. They also provide a model for exact experimentation. In the best of these experiments a control group has been treated in exactly the same manner as the experimental group except for the passage of electric current. The experimental procedure was clearly specified and an appropriate statistical technique was used. If these features are sought for in the experiments which have so far used human subjects the number of studies which meet the requirements is embarrassingly small. Indeed the literature, which at first sight is large and varied, can be made to vanish altogether if one insists that a *placebo* treatment ("pseudo shock" in which the electrodes are applied but no current is passed is a common feature of animal research) should form part of an adequate experimental design. An example of an experiment using this type of control in human subjects is provided by a recent research into the efficacy of insulin shock (Ackner, Harris and Oldham, 1957). There is no reason to suppose that a similar procedure is impossible in the case of E.C.T.; it has, indeed, been used by Brengelmann (1959).

Many of the experiments which are cited as evidence for psychological changes after E.C.T. do not satisfy even less exacting requirements. Many studies have no control groups at all and, in other cases, the control subjects are not patients but normal persons. In other studies there is no statistical analysis of the data which may nevertheless be quoted as an instance of "cognitive impairment" or "greater ability to invest emotion." It is the more surprising to find this state of affairs as many experimenters have wished to

examine the retention of previously learned habits after E.C.T. It is in this area that experimental psychology has for long had a considerable technique. But from the point of view of clinical research Ebbinghaus has lived in vain.

In view of these criticisms a considerable part of the work upon human subjects has been omitted from this review. In particular studies which make no statistical analysis of the data, or which use the results of tests such as the Rorschach, whose validity is unknown or dubious, have not been discussed in great detail. The studies cited have been divided into two sections: clinical and psychological. "Clinical" studies are based upon observations made without any special techniques to measure behaviour and with no particular research design beyond the obvious comparison of "before and after" shock. A great number of observations have been made in such circumstances. Only a small number of them are cited in this paper for their relevance to psychological studies. Thus experiments which compare the use of different relaxant drugs, *glissando* shock and conventional shock and the like, have been omitted.

Clinical Studies

THE GROSS EFFECTS OF E.C.T.

Immediately following a grand mal convulsion the subject no longer reacts to any kind of stimuli. There is a gradual return of psychological functions during which signs typical of "organic" disturbance can be evoked, e.g. perseveration, retrograde amnesia (Stainbrook, 1944; Flescher, 1942). But within hours these alterations have disappeared and the individual's psychological functions are apparently at the previous level again.

RECOVERY RATES AFTER E.C.T.

A large number of studies have included figures for the recovery rate of patients following a course of E.C.T. Alexander (1944) has pointed out that, as no limit has been generally accepted for the period of time in which changes of mental state may be attributed to shock therapy, remissions occurring within two to three months of the treatment have been counted as successes. He proposed as a criterion of success a thirty-day period during which the patient must leave hospital. In fact, some reports cover periods of up to twelve months.

Many of the early papers made comparisons between various diagnostic groups or between Metrazol and electrically induced convulsions. The comparisons between diagnostic groups indicate the success of E.C.T. in treatment of affective psychoses and the comparative failure with schizophrenia. Smith, Hughes, Hastings and Alpers (1942) gave the following figures for recovery rates: involutional melancholia, 85 per cent; manic-depressive psychosis (depressive phase), 72 per cent; manic-depressive psychosis (manic phase), 70 per cent; and schizophrenia, 0 per cent. These figures were not based on large numbers but later results have generally shown close agreement with them. Smith, Hastings and Hughes (1943), for example, found that E.C.T. was most effective for involutional melancholia (recovery rate = 70 per cent) and least effective for schizophrenia (recovery rate less than 30 per cent). Alexander (1953) examined the outcome in one hundred consecutive cases treated with E.C.T. for a period of five years. The only factor which he found to be related to the final state of the patient was diagnosis; five-year remissions occurred twice as frequently in non-schizophrenic patients as among the schizophrenics. Batt (1943) found a recovery rate of 87 per cent in depressive psychosis. Kalinowsky (1943) reviewing the results of 1,500 cases found a recovery rate in the affective disorders larger than 80 per cent. He considered the duration of illness an important variable in cases of schizophrenia. The longer the illness the less likely was any improvement. Slater (1946) reported that claims have been made for a recovery rate of up to 90 per cent in involutional melancholia.

In a number of instances figures are available for both treated and untreated groups of patients. Bagchi, Howell and Schmale (1945) contrasted fifty-four neurotic and psychotic patients who were given shock therapy with sixty-four similar cases who were not shocked. Both groups also received other treatments. In the shocked group recovery was recorded in 49 per cent of the cases; 30.5 per cent of the non-shocked group recovered. These recovery rates differ significantly at the 0.02 level of confidence. Huston and Locher (1948) give figures for a shock group com-

prising seventy-four depressives and a similar group of eighty patients as controls. The results were as follows—

	Control (N = 80)	Experimental (N = 74)
Recovered	63	65
Suicide	6	1
Remained depressed .	7	7
Died	4	1

The recovery rate favours the treatment but the difference is not significant. But though the gross recovery rates are alike the time necessary for recovery seems to be reduced by the intervention of treatment. The median time for recovery in the experimental group was nine months and, in the control group, fifteen months.

Karagulla (1950) presented an analysis of nine hundred and twenty-three cases treated both with and without E.C.T. She reported no statistical superiority for the treatment but only a greater "clinical improvement" in the treated group. Slater (1951) attacked these conclusions and using the same figures was able to show that E.C.T. led to a real improvement in the recovery rate. In a similar study Currier, Cullinan and Rothschild (1952) compared data of untreated female schizophrenics and similar treated cases. In the untreated group 30 per cent recovered and in the treated group 75 per cent recovered. Despite the differences found for the gross recovery rate it seems clear that E.C.T. shortens the course of the illness.

This type of study, in which treated and untreated groups are compared, provides a better basis for measuring the effect of E.C.T. than studies in which an E.C.T. group only is included. More work is necessary, with clear definition of time intervals and exact criteria of improvement, before the contribution E.C.T. makes to recovery over and above a natural remission rate can be assessed. The inclusion of untreated control groups, as in these studies, results in a rather more conservative estimate of the efficacy of E.C.T. than the crude recovery rate alone. It has been suggested that E.C.T. is effective only in speeding up remission which has already begun in a depressive illness. At present no definitive opinion can be passed on this possibility though the results of Huston and Locher are consistent with the idea.

CLINICAL SIGNS AND THE OUTCOME OF E.C.T.

The gross recovery rates after E.C.T. reported in the literature vary from study to study. Part of this variation might have been due to variation in the type of patient selected for treatment. Very often the

treated group has included all varieties of psychotic illness. A number of researches have indicated that therapeutic outcome is also related to some clearly defined variables other than diagnosis. These factors recall features of some of the animal experiments upon retention.

Batt (1943) examined the outcome of E.C.T. in one hundred cases by dividing them into groups. He found that the recovery rate was highest if the depression treated was the first attack of the illness (96.5 per cent). In such cases he also found that a much shorter period of hospitalization was necessary even if the illness was left untreated. In other types of case, for example recurrent depression, menopausal depression, the recovery rate was rather lower. He concluded that about 90 per cent of all first treatments are successful and that 13 per cent of all cases relapse and need further treatment. The worst prognosis is for chronic cases.

Gralnick (1946) found that treatment is most effective when the patient has not had a long illness. He found a higher recovery rate in patients who had been ill for less than a year. Currier, Cullinan and Rothschild (1952) compared two groups of patients to show the effects of age, duration of illness and acuteness of onset. They found a higher recovery rate among the patients whose illness has been of short duration (less than a year), who were under forty and where the onset of the illness had been acute. Herzberg (1954) made a similar study which included an evaluation of the patient's status one year after shock treatment. He found that a short illness (less than six months) and marriage were favourable prognostic signs, but that a long illness was unfavourable; acuteness of onset was also important. Hobson (1953) examined the connexion between the outcome of treatment and one hundred and twenty-one items of clinical information. He found a suggestive or significant association for twenty items and devised a scoring scale which, in his study, gave a misclassification of outcome in only 21 per cent of his cases. Sudden onset and good insight were the main signs for a favourable prognosis; depersonalization and hypochondriasis were the principal unfavourable signs. The signs isolated in the analysis are considered, in many instances, to be relevant in cases not treated by convulsive therapy.

RETENTION AND E.C.T.

The loss of memory shown in the period which immediately follows E.C.T. turned interest to the possibility of long-term defects in memory. Tooth and Blackburn (1939) noted that some patients complained of memory defect for periods of up to six months after treatment. A considerable number of observations of this type have been made in clinical practice.

Lowenbach and Stainbrook (1942) used the Rorschach test and Wertheimer designs to investigate memory in the period immediately following shock. They suggested that memory for remote events is less influenced by shock than memory for recent events. For example, a woman patient gave her maiden name after treatment. Levy, Serota and Grinker (1942) noted an "intellectual impairment" after shock which lasted for up to three weeks; this judgement was made on the basis of psychiatric assessment. Smith, Hughes, Hastings and Alpers (1942) noted memory defects which, though not permanent, may last for months. Brody (1944) reported on five cases in which E.C.T. appeared to have led to prolonged memory defects for familiar material.

Alexander (1953) reporting the effect of E.C.T. upon a normal subject found that post-shock amnesia was confined to an unpleasant incident which had occurred immediately before E.C.T. This he considered as evidence for the notion that E.C.T. heightens the personality's defence mechanisms, such as repression. A series of such alterations leads to recovery. Meyer (1951) considers that the post-shock amnesias have no significance for the success of therapy except in cases where there may be a total amnesia for psychotic events which permits a complete reconstruction of the personality.

Interestingly enough, some hypnotic phenomena, such as post-hypnotic suggestion and regression to earlier ages, persist, through a shock, in weakened form. The shocks were given at the end of a hypnotic trance with the patients' consent (Bowers and Berkowitz, 1953).

PHYSICAL EFFECTS OF E.C.T.

A considerable number of cases have been reported in which brain damage has been observed and could have been attributed to E.C.T. Madow (1956) summarized the data available from these observations made on thirty-eight cases and gave additional information on four further cases. As one might expect the topic is treated in the medical literature mainly for the possibility of E.C.T. causing death. The findings in the majority of cases were similar to those found in animal studies. The greatest number of changes were found in the vascular system and generally consisted of small haemorrhages. But the changes are generally held to be reversible within a fairly short period, except in cases where the patient has cardiac or vascular disease.

Changes in brain function have been examined in EEG records taken from patients in the period after treatment. Levy, Serota and Grinker (1942) found that post-shock neurological examination gave negative results but EEG records showed cerebral disturbance, which, in the most marked cases, were of

an epileptoid variety. These signs disappeared, usually in a few weeks after treatment, though some patients showed them for six months. Clinical tests of mental status showed an improvement uncorrelated with EEG changes. In a similar study Pacella, Barrera and Kalinowsky (1942) noted that generalized convulsions unlike petit mal seizures, led to marked EEG changes. The longer the series of shocks the more marked and persistent were the changes. The abnormal features of the EEG record disappear in a few weeks once treatment is stopped. Roth and McClatchey (1951) obtained EEG records from post-E.C.T. patients while the patients were under the influence of the drug thiopentone. This drug reduces the activity of the midbrain. The authors conclude that the enduring and cumulative effects of E.C.T. are exerted primarily on a subcortical centre.

The EEG studies made after E.C.T. have been reviewed by Chusid and Pacella (1952). Among their conclusions they state that no correlation is found in the published reports between the post-shock EEG pattern and the clinical response to treatment, or the degree of memory disturbance.

A number of recent studies have emphasized the general effect of E.C.T. in humans (Aird, Strait, Pace, Hrenoff and Bowditch, 1956; Weil-Malherbe, 1955; Bassett and Ross Ashby, 1954). The mode of action of E.C.T. remains unclear however. Weil-Malherbe found changes in adrenaline level as a consequence of shock which he attributed to autonomic activity. Bassett and Ross Ashby found that the P.G.R. of treated patients does not habituate to sudden stimulation as it does in untreated controls. They attribute this to a direct cortical action rather than to an emotional mechanism. In this connexion an interesting case is reported by Guze, Winokur and Levin (1956) in which E.C.T. was successful even though the patient's adrenal cortex was not intact or functional.

RATIONALES FOR TREATMENT

No generally accepted explanation of the action of E.C.T. is available. Parsons, Banet, Keating and Lawrence (1955) remark in the course of a survey of the treatment: "Electroshock as a therapeutic technique is the product of accident and empiricism." The most characteristic psychiatric explanation is based, in one form or another, upon psychodynamics. Treatment is supposed to be, say, anxiety-producing, and therefore leads to more effective repression of the symptoms. This view has not led to any experimental verification up to the present though there is anecdotal evidence in support of it.

Another class of theory which is frequently put forward to explain the psychological consequences of E.C.T. has a physiological basis. E.C.T. is held to

cause alterations in brain function which in turn lead to changes in mental states. It is doubtful whether enough is known at present of the physiological changes induced by E.C.T. to provide a detailed basis for such an explanation. And even if these details were available the connexions between brain function and mental states are not yet sufficiently established for one to say what changes in mood should result from any particular physiological change. Like many other psychiatric theories the view embodies an extensive programme of uncompleted research.

A typical example of this view is provided by Myerson (1943) who suggested that the convulsions and shocks "knocked out" the brain and enabled the pathological state to be "forgotten." This theory is fairly representative in its use of a simple physiological "forgetting" but, in view of the temporary nature of the changes in brain function, it would appear to need reinforcement by some account of what prevents the revival of pathology. However Kahn, Fink and Weinstein (1956) claim to have shown that the short-term response to treatment is related to signs of brain damage elicited under sodium amytal. The whole subject needs further investigation.

Psychological Studies

Experiments whose main data are taken from psychological tests are included in this section. The changes which E.C.T. is said to induce, particularly in personality and mood, would appear to provide an excellent topic for psychological investigation. In fact, very few studies have made use of psychological tests in an appropriate way and fewer still have used an experimental design which can show the intended result. Many of the references given in the literature turn out to be articles which contain no tests of significance and no control groups. It is, in fact, alarming for the reviewer to find the results so often quoted fading into insubstantiality. But such is the case and consequently no set of data analogous to that derived from animals is available for discussion.

TESTS GIVEN BEFORE AND AFTER E.C.T.

Batteries of tests given before and after E.C.T. have been used most often in attempts to show the effects of E.C.T. However, in order to establish that E.C.T. is the effective agent in producing changes in score one requires data from a control group tested at the same time or test-retest data for the battery in question obtained from comparable subjects.

For example, the Rorschach Test has been used by several experimenters in order to show post-shock personality change. An early study by Stainbrook (1941) suggested that as time elapsed after a series of shocks so the responses altered. Several studies

compared results from before and after the shock treatment. In these experiments no non-shock control group was used and generally no statistical treatment is given. Even so very little is claimed for the results, though the pre- and post-treatment results are thought to be different (Kelley, Margulies and Barrera, 1941; Beck, 1943; Pacella, Piotrowski and Lewis, 1947; Rees and Jones, 1951). Beck concluded that "shock therapy is not as effective in reaching the inner personality as either spontaneous remission or deep-searching intensive psychotherapy." In general the changes seemed to reflect little more than the customary post-shock confusion in its varying degrees.

Intellectual impairment has also been looked for. Stone (1947) proposed that each shock causes an immediate cognitive loss from which the patients recover in some three to four hours; but a series of such shocks is cumulative in effect as, each time, recovery is assumed to be a little less complete. He examined this view by using both forms of the Wechsler Memory Scale. The parallel forms of the test were given to an experimental group of patients before and after a treatment series of shocks. A control group of patients was given the test one day after a treatment series of shocks and again three weeks later. The experimental group dropped significantly on all but one subtest. The control group on the other hand showed a significant gain in score. Normal control data ordinarily show little change from Form I to Form II on retest. The Wechsler Memory Scale correlates highly with tests of intelligence (e.g. the Army Alpha test) so this finding appears to reflect a genuine cognitive impairment. These results, though consistent with Stone's view that shock leads to *gradual* decline does not in fact prove it. A complete proof would require more tests to be given during the shock series.

Summerskill, Seeman and Meals (1952) found no significant change in Wechsler I.Q., thirty minutes after a single electroshock, which suggests that the result of a single shock may be difficult to demonstrate by relying solely on a deterioration of performance. The *absence* of a significant *improvement* might emerge if there were an untreated control group for comparison. The same patients showed disorientation and impaired motor performance on the Whipple-Healy tapping test.

Huston and Strother (1948) tested patients before and after treatment. They found a slight improvement from pre-shock test to post-shock test on the Babcock and Shipley-Hartford scales but there is no data from untreated controls to aid in assessing this. At later follow-up the results of the treated group did not differ significantly from those of a set of matched normal controls, so that a long term impairment seems unlikely.

Fisher (1949) used both cognitive tests and a questionnaire to assess mood in an experimental design which depended upon the comparison of improved and unimproved patients who had been treated with E.C.T. Significant improvements in Wechsler I.Q. scores fourteen days after treatment in the group of patients who were rated as improved were mainly due to alterations in the comprehension, similarities and digit symbol subtests. The I.Q. scores in the unimproved and slightly improved groups of patients showed a small non-significant decline on retest. The pre-shock pattern of scores was similar in all three groups of patients and was of no assistance in predicting outcome of treatment. Brower and Oppenheim (1951) also report an improvement on Wechsler and Mirror Drawing scores after E.C.T. but give no details concerning tests of significance, results of a control group or the interval between tests which would enable an assessment to be made of this finding.

Beran, Perkins and Scollon (1952) compared the scores of the Wechsler Memory Scale and the Revised Beta Examination in both treated and untreated groups of neurotics and schizophrenics. The treated group was tested before and after E.C.T. and the untreated group was tested at comparable time intervals. Both the experimental and control groups showed a gain in I.Q. score on retest and the difference in the amount of gain shown by the two groups was not significant. Michael (1954) found that the Binet word naming score declined during treatment (whereas the score of a control group improved) but rose again later. Stieper, Williams and Duncan (1951) found an improvement in the abbreviated C.U.S. I.Q. but no change in Wechsler I.Q. In this case the control subjects were not mental patients, and the interval between the shock series and retest was not constant. Gurevitz and Helme (1954) examined the results of E.C.T. in sixteen child patients with schizophrenia. Tests of intellectual function (Binet, a non-language test, and the Goodenough) showed a drop in score immediately after shock (twenty-eight to forty-eight hours) but a later test showed an increase above the initial level.

A major variable in these studies (which is not always explicitly specified) appears to be the time interval between shock and test. The results of Stone and of Michael indicate that testing close after the shock tends to produce scores lower than pre-shock scores. But in other studies, where longer time intervals were allowed, either no change or a practice effect may have occurred. The general conclusion of Kalinowsky and Hoch (1952) seems valid: "Most of the psychologic investigations on human patients as well as animals are interesting scientifically, but only confirm the temporary memory impairment which is seen by the clinician."

MEMORY AND E.C.T.

The experiments upon memory and retention after E.C.T. have, on the whole, been better arranged. An early experiment by Zubin and Barrera (1941) who used paired associates showed that shock diminishes recall. Moreover, under control conditions both "remote" and "recent" associations were remembered but with a slight advantage to the recent associations. After shock the advantage of the recent associations no longer appeared which implies that shock has a greater effect on more recently acquired habits. Sherman, Mergener and Levitin (1941) on the other hand reported no significant change in memory scores but used no control tests to substantiate this finding. Rodnick (1942) trained schizophrenic patients on two incompatible habits successively. Then one group was given Metrazol shock; on retest the Metrazol group showed a significantly higher proportion of reversions to the earlier habit. Mayer-Gross (1943), who examined post-shock amnesia, found a similar retrograde effect; pictures shown early in a pre-shock series were either recognized or recalled more often than those shown later in the series. But if testing were postponed, say twenty-four hours after treatment, then this effect was very much diminished. He pointed out the similarity between these results and those found in "retroactive inhibition" experiments.

The most comprehensive experiments using human subjects were made in this area by Janis (1950). He intended to investigate specific psychological changes which persist longer than the immediate post-shock "organic syndrome." He required both experimental and control subjects to give long circumstantial accounts of their lives. On retest (which in the case of the shock group was four weeks after the shock series) the subjects were asked to repeat their histories and were then interviewed for detailed points. Every member of the E.C.T. group was unable to recall some previous memories and some, in fact, failed even to recognize descriptions of incidents from their own lives. Such failures were rare in the control group. Five cases in the experimental group which were followed up for two and a half to three and a half months showed such specific amnesias during the entire period. Janis suggests these particular circumscribed amnesias are special cases of a general retroactive inhibition which are maintained by special motivational factors. In a further study the memory of treated patients was again shown to be poorer than that of controls. An additional measure showed that the latency of even the accurate memory responses was longer in the experimental group (Janis and Astrachan, 1951). Janis, in his experiment, gave questionnaires designed to measure affective change due to E.C.T. The treated group showed its greatest change in self-deprecatory attitudes which became less marked.

Worchel and Narciso (1950) examined the effects of shock given immediately after, and one hour after, learning nonsense syllables. They were not able to demonstrate a retrograde amnesia. Carter (1953) confirmed Janis's findings. Further, by classifying the memories into "pleasant" and "painful" he was able to show that the painful memories were forgotten significantly more often than the pleasant ones. He also found that more recent memories were forgotten. The differential forgetting of pleasant and unpleasant experiences is commonly found in normal subjects under ordinary conditions. E.C.T., though it alters the amount forgotten, does not appear to alter other features of the memory process. Bogoch (1954) examined the behaviour of post-shock amnesic patients under Sodium Amytal. Seventeen out of twenty-one cases demonstrated an improvement in recall in these circumstances. Bogoch attributed the apparent inability to remember after a shock series to an inability to verbalize except under the drug.

E.C.T. AND MOTOR PERFORMANCE

Changes in motor performance have been noted after E.C.T. Generally speed, or rate of output, has been used as measures of performance. Hetherington (1952) observed changes in the motor aspects of drawing after shock. He put forward the view (1956) that E.C.T. produces an increase in the output of muscular work. This conclusion was based on a comparison of the performance of patients and normal controls on a variety of psychomotor tests given before, during and after a series of electroshocks. Since, however, the initial scores of the treated group were poorer than those of the normal controls they had more room for improvement and could display the greater practice effect which is possible in the early development of a skilled performance. Landis and Clausen (1955) found rather similar results in making a comparison of groups of patients undergoing different treatments. They offer an explanation in line with that outlined above: the improvement found in the E.C.T. group may have been a consequence of the greater benefit from practice which is possible where there is an initial retardation.

Foulds (1952) provides data upon this point. He gave a modified form of the Porteus Mazes in which the emphasis was put upon speed of performance to a group of patients undergoing E.C.T. The mazes were given twice before and twice after treatment. There was a striking improvement in speed of performance on the second trial before treatment, a decrement on the third trial given after treatment, and a further improvement on the last trial. The same procedure was used by Campbell (1957) with the addition of a control group which received no

treatment between pairs of trials. In this case the decrement in speed of performance on the third trial was again found but only in the experimental group and may be attributed to E.C.T. In the same study a considerable variety of motor tests was given to both the experimental and control groups. At retest both groups showed an improvement in speed of performance on the majority of tests, no doubt the result of practice during the pre-treatment administration of the test. However, when the size of the improvements made by each group was compared it was found that the untreated group tended to show larger improvements in speed of performance and that a greater number of the subjects who had been given shock treatment showed a performance decrement. The effect occurred both in those patients who showed an improvement in clinical state and in those who did not. The results suggested that E.C.T. leads to a loss in speed of performance which may be masked by improvement from an initially retarded score unless a group of similar patients are used as control subjects to indicate the improvement which can be attributed to practice.

Callagan (1952) used a large battery of tests, including several psychomotor tasks, to examine the influence of E.C.T. in an experimental group. He gave the battery on three occasions and had an untreated control group which he tested at the same time intervals. He did not achieve his main aim of providing a prognostic scale using cognitive tests but he obtained some interesting results nevertheless. On a manual dexterity test the treated group showed a decrement in performance after shock whereas the control group showed an improvement. He also used a "slowness of writing" test as a measure of motor control. The subject is asked to write as slowly as he can; Callagan found that improved motor control after E.C.T. enables subjects to write more slowly. Campbell (1957) did not repeat this finding.

E.C.T. AND PERCEPTION

The effect of E.C.T. upon perception was examined by Williams (1950) in a well-controlled experiment. She found that responses to ambiguous stimuli were more readily aroused if some similar stimulus had been shown for identification immediately before E.C.T. That is to say, responses after E.C.T. are facilitated by previous performance even if this is not consciously remembered. In this case the previous experience has presumably served as practice and, as in the case of motor tests, the practice effect survived E.C.T. Responses to sets of stimuli which had not been presented before treatment were delayed by E.C.T. and occurred only when the "ambiguous" stimuli approximated more closely to a readily discriminable outline.

Fischelli, Rockwell and Clarke (1955) compared spontaneous rates of reversal of perspective found in ambiguous perspective figures before and after E.C.T. The average rate of reversal was reduced in the shock group but remained unchanged in a control group. This change was largely due to the effect of E.C.T. upon those subjects whose rate of reversal was fastest in the original test. This result may be explained in terms of Kohler and Wallach's "satiation theory" (Fischelli, 1947) which supposes that rate of reversal is determined by a neural process of "fatigue" or "inhibition" of some kind. Other researches have not found this change (Philip, 1953; Campbell, 1957); also the rate of reversal in psychiatric patients is generally slower than in normals (Eysenck, 1952). Such differences in result may depend upon the experimental conditions and procedure. Rate of reversal has been shown to be influenced by variations in both of these (Eysenck, 1952; Brown, 1954). Callagan (1952) found some significant changes before and after E.C.T. in rate of reversal of perspective when the subjects were given instructions either to maximize the rate or to take a passive attitude; but no significant changes were obtained upon a second passive trial and when the subjects were told to attempt to reduce the rate.

Brengelmann (1959) examined the effects of single and repeated electroshocks upon visual learning. He gave a test, in which the subjects were asked to reproduce designs which had been exposed briefly to them, at intervals of thirty minutes, four hours and twenty-eight hours after the first, third, fifth and seventh treatments. The first three shocks in the series produced no apparent learning deficit but five and seven shocks both led to impairment. This result appeared to be due to the creation, by repeated shock, of an organic syndrome. In a further experiment Brengelmann (1959) was able to show, by comparing a control group with his experimental group, that shock reduced the learning in the experimental group from the beginning of the experiment. The disturbance due to shock showed particularly in measures of expressive movement. Within any particular test session the electroshock did not alter the shape of the learning curve but over a series of tests the shock group either improved less than the control group or else showed an actual deterioration.

Two experiments which examined the emotional aspects of perception have been briefly reported. Teicher (1953) used tachistoscopic exposure of emotional and non-emotional words to show that an untreated group failed to differentiate the words but a treated group reacted differentially to the two categories. Korngold (1953) found that E.C.T. abolished a stimulus sensitization set up by stopping patients from completing a task. In each case the

prevailing pre-shock reactions of the subjects were altered by shock.

PROGNOSIS

A number of attempts have been made (some as part of some of the experiments described earlier) to establish prognostic signs for E.C.T. Attempts using cognitive tests have been unsuccessful for the most part. The most encouraging of such experiments have used the M.M.P.I.

Pearson (1950) analysed the pre-treatment results on the M.M.P.I. of twenty-nine male schizophrenics. The treatment was a failure when extreme (high or low) scores were found in the depression scale or when high scores were found on the schizophrenia scale or any three scales together. The same results were found in a cross-validation group of fifteen cases. In a subsequent experiment, though the general tendencies held good the scoring scale did not repeat its usefulness (Pearson and Swenson, 1951). Feldman (1951) produced a prognostic scale from the M.M.P.I.

which worked well on independent groups also. Scherer (1951) found improvement after E.C.T. to be related to motor speed and "abstraction." Carpenter (1953) later found that the items of Feldman's scale were rated by "psychologically sophisticated judges" as related to "ego-alien extrapunitive-ness,"

It should be pointed out that these studies of prognosis have proceeded by correlating individual test items with outcome in groups of treated cases. It is possible that they may relate to improvement as such, rather than to improvement under E.C.T. In these cases too an untreated control group is necessary for an adequate assessment of the consequences of E.C.T.

Fisher (1949) and Campbell (1957) both found that, when the Hildreth Feeling Scale was used before and after treatment there was a slight tendency for the improved patients to be those who had shown the greatest degree of pre-shock depression. This tendency also appeared in Campbell's control group which received no treatment between test and retest.

DISCUSSION

The results of the experiments carried out using human subjects may be assessed by considering the four objects of psychological research mentioned in the introduction to this chapter. No work has been done by psychologists to determine the efficacy of E.C.T. in general terms. In this respect E.C.T. is no worse off than other forms of psychiatric therapy. Investigations of this type present many opportunities for the exercise of psychological virtues such as "quantification," "objectification" and the like, which would provide alternatives to the traditional categories used to describe the outcome of a treatment. Nor have psychologists directed attention to the necessary comparison between a "natural" remission rate in depressive illness and the recovery rate following E.C.T.

The psychological changes brought about by E.C.T. have been examined by a large number of investigators. Generally speaking complex, multifactorial tests such as the Wechsler and the Rorschach have been used, and the majority of the experiments have been directed to the cognitive aspect of the changes. The results have indicated some restricted memory impairment which may be permanent, at least a temporary cognitive loss and a reduction in the benefit derived from practice on motor tasks. At present, largely because of methodological weaknesses, the psychological findings do not lend themselves to any exact specification of the changes wrought by E.C.T. It seems fair to conclude that, in this instance, the clinical observations have been confirmed but have not been refined.

Very few experiments have been designed to test explanations of the effects of E.C.T. and these have not been conclusive. Finally, the experiments concerned with prognosis, despite their initial cross-validation successes, are unlikely to be of general practical value unless a more rational basis for the results can be found in view of the differences which exist in psychiatric practice.

In view of the rather meagre results from the experiments with human subjects the best lead for further work seems to be the comparison of the animal and human experiments. It was remarked earlier that, in detail, the comparison of the two sets of results was discouraging: in contrast with clinical experience the animal experiments suggested that permanent cognitive changes may result from E.C.T. and emotional changes may be short-lasting. But the discrepant results and the variables in these experiments provide indications which may lead to more fruitful research in human subjects. For example in the case of cognitive changes it was shown in rats that the level of task difficulty used, and the measures of performance taken, had an important influence upon the results. In the case of emotional changes the time factors were shown to be of importance in a way which brings to mind the clinical observations respecting the age of an illness as a variable which influences the outcome of E.C.T.

The comparison can also be used to suggest topics in which animal research may be extended. The variables from clinical observation—age of the

illness, the age of the patient, the onset of the disease, etc.—should be capable of reproduction in an animal experiment designed to provide information concerning their relative importance. A wider variety of animals should be used in experiments. The rat makes an excellent *point d'appui* but the examination of emotional changes might benefit if an animal were used which permits the construction of a better paradigm for depression than the purely situational anxiety that has been used up to the present. A variety of animals would also make more detailed physiological investigations possible. Experiments along these lines might also reduce the discontinuity which exists at present between the animal and human results.

The comparison suggests some major topics for research with human subjects. The cognitive consequences of E.C.T. may become less uncertain if two cues are taken from the animal research. The measures of impairment need to be refined and extended as the I.Q. scores which have been used may obscure the detail of the changes. In several experiments changes in subtest scores are reported which may well indicate quite specific alterations in function which deserve further investigation. Another feature of the cognitive changes which needs study is the time of the changes. No adequate data exist for the course of, and recovery from impairment. Data on this point might become of practical importance as well as being theoretically interesting in view of the large number of shocks which are given in some cases.

The simplest psychological explanation of many of the results of E.C.T. is that which likens the effect of E.C.T. to retroactive inhibition. It is supported by the observations concerning the age of the illness noted above and by the results of several experiments upon animals, but the idea has never been worked out in detail. Moreover a "gap" exists between the experiments, which have dealt with periods of a few hours, and the facts of the illness which may cover a period of months. No satisfactory large-scale experiment has tested the hypothesis in human subjects. The usual explanation of retroactive inhibition is based on the notion of "interfering" responses. In the case of E.C.T. these must presumably be older normal responses which are reactivated (in contrast to "liberated") by the treatment and supersede the abnormal state, perhaps reinforced by a relearning process of some kind. A set of experiments designed to examine specific hypotheses concerning cognitive, motor and emotional responses would be necessary to demonstrate the theory in detail.

It also seems necessary to extend the experimental measurement of affect and prevailing mood. As E.C.T. is intended to act primarily upon mood the

almost universal neglect of this aspect of post-shock change is surprising. But if affect is to be subsumed under the retroactive inhibition model more exact estimates of changes in mood will be necessary. This may also remove part of the difficulty in regarding mood as sharing some of the features of a habit.

The success of research in this field appears to depend upon the adoption of techniques from experimental psychology. Clinical research requires exact hypotheses, adequate control groups and appropriate experimental design as much as any other psychological investigation. Until the example set by the minority of experimenters becomes the general rule theoretical advance will be hampered by lack of adequate data.

CHAPTER 17

The Effects of Drugs on Behaviour¹

D. TROUTON and H. J. EYSENCK

1. INTRODUCTION: PROBLEMS AND METHODOLOGY

THE experimental study of the psychological effects of drugs appears to have begun with the work of Kraepelin whose work and methods were soon taken up by other psychologists such as Rivers (1908) and Hollingworth (1912). Several reviews, such as those by Poffenberger (1914, 1916, 1917, 1919), Darrow (1927, 1929), Shock (1939), Spragg (1941), and Gray and Trowbridge (1942), have summarized the large body of work done in this field, but on the whole it cannot be said that "psychopharmacology" has received much recognition in psychological textbooks, nor is it usually represented in courses of lectures in abnormal psychology.

One of the reasons for this neglect may lie in the fact that work in this field almost inevitably must involve workers in several specialities. Several symposia on psychopharmacology have appeared recently (e.g. Abramson, 1955, 1956, *Amer. J. Psychiat.*, 1952, *Amer. Psychiat. Assoc. Res. Rep.*, 1955; *Ann. N.Y. Acad. Sci.*, 1956, *Chlorpromazine and Mental Health*, 1955; Cholden, 1955, *J. Nerv. Ment. Dis.*, 1955, *J. Pharmacol.*, 1956; Kline, 1956; Miner, 1955; Olds, 1957), and in all of these, contributions are made by a variety of different scientists including chemists, pharmacologists, biochemists, electrophysiologists and psychiatrists, as well as psychologists. The subject obviously occupies one of those borderlands between sciences which it is nobody's particular job to cultivate, but which, nevertheless, may be all the more interesting and important for that.

This review will be concerned with the behavioural effects of some of the more commonly used drugs, and we will be concerned particularly with the quantitative experimental analysis of these effects. To help to fill in some of the gaps, qualitative and clinical observations on psychiatric patients have sometimes had to be included, as are also some experiments on animals, where these are thought to contribute to our knowledge of the effects of the drugs in man.

Table XVII.1 lists some of the main factors influencing the subject's response to drugs. Most of the items will appear obvious, but nevertheless, many of them have frequently been neglected in past studies. Among the most important of these variables is the interval which is allowed to elapse between the administration of the drug and the commencement of the test; another is dosage. As regards the interval, we may wait until certain objective signs appear in the subject, or until subjective changes are reported; the other alternative is to use a fixed interval. As regards dosage, this may either be determined by reference to body weight or may be given in fixed amount; a third method, which is used particularly with intravenous barbiturates, is to continue the slow injection of the drug until certain signs occur, such as slurring of speech. Both dosage and interval may thus vary for different subjects.)

Where subjects do not differ much in weight, or where the drug is selectively absorbed by certain tissues, e.g. in the brain, administration on the basis of body weight is probably less important than in the case of such drugs as alcohol, which is distributed throughout all the tissues and fluids of the body, and where a given dose would consequently be more diluted in the blood of larger subjects.

The role of variables such as age, sex, and mode of administration is fully discussed in works on pharmacology (Goodman and Gilman, 1955). Psychological factors such as those involved in the effects of *placebos*, the relation of personality to drug effects, and the

¹ This chapter was discussed by us in great detail before the first draft was written by Dr. D. Trouton. Several drafts followed but before the chapter could be completed Dr. Trouton's tragic death made it necessary for the editor to play a much more active role in the actual writing than had been envisaged. The whole of the first part was rewritten and much of the rest was considerably altered, usually by shortening it, occasionally by addition. An explicit statement of the dimensional hypothesis was added. It is impossible to know whether Dr. Trouton would have agreed with all the changes, and the new points added, and it seemed fairest to him that the editor should assume responsibility for his part in the chapter in a formal manner.

TABLE XVII.1
THE MAIN VARIABLES INFLUENCING DRUG
EFFECTS

1. *Nature of the Drug*

Preparation (including concentration, vehicle of administration and whether disguised).
Mode (oral, intravenous injection, etc.) and rate of administration, absorption and excretion.
Dosage (according to body weight, or the same for all).
Interval before testing.

2. *The Subject*

Personality (including intelligence, extraversion-introversion, neuroticism, suggestibility, etc.).
Familiarity with the situation and the amount of stress occasioned by it.
Practice; fatigue; motivation.
Tendency to react to *placebos*.
Psychiatric state, and its duration.
Age, sex, physique, height and weight
Present state—
General state of health, nutritional status, sleep.
Conditions of work, e.g. temperature, humidity, oxygen lack.
Diseases, disabilities (e.g. fever, thyrotoxicosis, liver or kidney damage) or effects of operations, etc. (e.g. leucotomy, concussion).
Time of day.
Interval since last meal (if drug given orally).
Recent medication with other drugs (e.g. sedation) or ingestion of drinks containing stimulants or depressants.
Previous experience of drugs—
Cumulative effect of some drugs (e.g. bromides).
Habituation, tolerance (including cross-tolerance)
Addiction.
Idiosyncrasy or hypersensitivity.

3. *The Social Environment*

Interaction with other subjects.
Activities required or permitted after administration of the drug
Suggestion.
Reinforcement of responses by the experimenter.

personality make-up of volunteers will be discussed below.

Placebos

In all drug experiments it is necessary to include a control group in the experimental design which is administered a "dummy" treatment, i.e. which is given pills or injections indistinguishable by sight, smell or taste from the genuine treatment, but containing only inert substances. (This control treatment, often (erroneously) referred to as *placebo* treatment, is necessary because without it we could not be sure that any effects observed in the experimental group were due to the drug and not to psychological factors such as suggestibility, expectation, and so forth. Such effects are very common and may be very strong. Beecher (1955) has compared the incidence of relief provided by dummy tablets in fifteen studies involving over one thousand patients and a variety of different

conditions; on the average one patient in three reported relief! He has also reported some thirty-five different "toxic" effects which have sometimes been so severe that in "double blind" studies, in which neither the doctor nor the patient knew whether the dummy or the drug treatment had been given, the code had to be broken only to disclose that the patient was merely receiving a quite innocuous mixture of sugar and flour.

Trouton (1957) quoted many studies showing that conditions such as asthma, hay-fever, coughs, headaches, tension, post-operative pain, the common cold, and daytime incontinence of psychotics have been benefited by a *placebo*. All these studies involve the comparison of the *placebo* with a supposedly effective drug, and in many instances the *placebo* was as effective as the drug under investigation. In at least three studies the *placebo* appeared slightly more effective.

These psychological effects may either add to, or subtract from, drug effect. The study of Jellinek (1946) in which he found that 52 per cent of headaches were relieved by a *placebo*, may be taken as an example of an additive effect because the psychological factor of taking a pill as such can apparently compensate for an inadequate dose of analgesic. The subtractive effect is less obvious; as an example we may quote a study by Wolf (1950). He administered ipecacuanha to a woman with *hyperemesis gravidarum* who was persuaded that her vomiting would thereby be relieved; it was, and the contractions of the stomach were also inhibited for a time.

Not all subjects of psychological experiments on the effects of drugs show reactions to dummy treatments, and it is possible that what have been called *placebo* reactors constitute a separate class of people whose presence can seriously interfere with the study of drugs. For instance, Beecher *et al.* (1953), carried out a comparative study of morphine, codeine and a *placebo*, and found that, if the *placebo* reactors were excluded, it became "possible to demonstrate significance where it had not been possible before." Jellinek (1946) appears to have been the first to advocate excluding *placebo* reactors in comparative studies of drugs.

It is not known whether the tendency to react to *placebos* is a unitary trait. It is possible that those who experience unpleasant "toxic" effects are not the same as those who are benefited by *placebos*. Jellinek (1946) claims to have found evidence for a U-shaped distribution there being "individuals who definitely tend to respond and individuals who definitely do not tend to respond to a *placebo*." But Lasagna *et al.* (1954) found that only 45 per cent (of sixty-nine patients) were consistent in their responses in a particular situation.

The question of personality correlates of *placebo* reaction is an interesting one but not one on which much work has been done. Lasagna *et al.* (1954) and Tibbetts and Hawkins (1956) have reported work suggesting greater anxiety in *placebo* reactors than in non-reactors. The possibility cannot be ruled out that primary suggestibility is operative here, particularly in view of the fact that Eysenck (1947) found this personality trait to be correlated with neuroticism and anxiety. An alternative hypothesis might be formulated in terms of learning theory. Glaser and Whittow

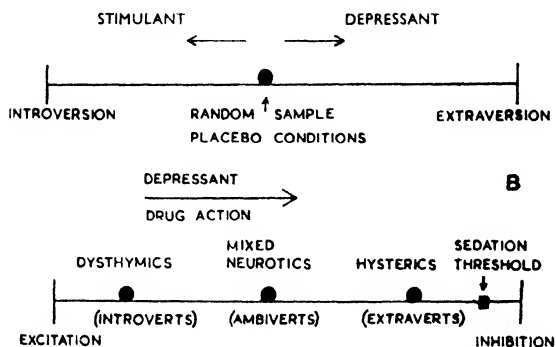

FIG. 17.1. TWO FUNDAMENTAL RESEARCH DESIGNS FOR THE STUDY OF DRUG EFFECTS

(1953, 1954) found that if subjects were repeatedly given *placebos* and required to fill in questionnaires recording their effects, there were positive responses at first (generalization from other learning situations) but these became fewer on each occasion (lack of reinforcement); when an active drug, similar in appearance to the *placebo*, was given, more symptoms were reported when *placebos* were next administered than when subjects had not received any previous medication (response generalization). If we take these results together with Franks's (1956) demonstration that introverts form conditioned responses more quickly, it would be possible to argue that the introvert, or dysthymic, would tend to acquire *placebo* responses more readily, and to lose them less readily, than the extravert or hysteric. At present it is impossible to decide between these two hypotheses, both of which may, in fact, be valid. There appears to be an important area for research here.

The Problem of Volunteers

• Much of the experimental psychological work on the effects of drugs has been done on volunteers, and there is some evidence that volunteers, particularly for drug experiments, differ in various ways from those who do not volunteer. This has been found to be the case in some studies of the personality traits of volunteers for interviews about sexual behaviour (Siegman, 1956). Riggs and Kaess (1955) compared

students who volunteered for a psychological experiment with those who had not; one of their findings was that the volunteers were significantly higher on the T and C scales of the Guilford S.T.D.C.R. questionnaire, "indicating respectively introverse thinking and moody cycloid emotionality." As Eysenck (1953) has shown, both these scales are good measures of neuroticism, so that it appears probable that more neurotic subjects are more likely to volunteer for studies of this kind. This conclusion is strengthened by a study (Lasagna *et al.*, 1954), in which a remarkably high incidence of severe maladjustment was found among fifty-six volunteers for a drug experiment at Harvard Medical School. Although the volunteers were students and supposedly normal, they included three psychotics, twelve neurotics, three psychopaths, an alcoholic, and at least four homosexuals! The authors point out that "much of the literature on marihuana, morphine, heroin, and similar drugs is derived from experience of 'volunteers' with unusual psychological orientation and imaginative, romantic proclivities. Without denying the 'reality' of responses in such people, it has proved scientifically unwise to assume that such responses are typical of those experienced by all individuals under the circumstances." Much of the literature on hallucinogens, particularly on mescaline, is subject to the same criticism. If it is not possible to use a random sample, it is clearly important to have some measure of the personality of the volunteers, and the type and degree of abnormality that may characterize them.

The Relation of Personality to Drug Effects

Drug experiments, as Eysenck (1957) has pointed out, may follow one of two paradigms. The two possibilities are illustrated in Fig. 17.1 which, for the sake of an example, deals with a particular hypothesis regarding the effects of stimulant and depressant drugs. The hypothesis, which will be discussed in more detail later, states simply that *stimulant* drugs will have *introverting* effects, whereas *depressant* drugs will have *extraverting* effects on the whole. The first and most obvious method of testing an hypothesis of this kind is clearly the one depicted in the top part of the diagram. If we are dealing with an experimental measure of extraversion-introversion which is not subject to strong learning effects, we would administer the three drugs (stimulant, depressant, and *placebo*) to the same random group of subjects on three separate occasions. Sequence effects would, of course, be controlled by some form of Latin square design, and analysis of variance would be used to sort out drug effects and practice effects. If a test had to be used which was subject to strong learning effects, it would be necessary to select three equivalent groups and to administer each of these three treatments to

one of the groups; analysis of covariance could be the appropriate statistical method.

It will be noted that in this type of design no attention is paid to individual differences between subjects. In so far as these exist they are relegated to the error term of the equation. The alternative design given in the lower part of Fig. 17.1 capitalizes on these differences by making use of the prediction of different reactions for different types of people. If we are able to define a sedation threshold (Shagass, 1956, 1957) along physiological lines as a point where inhibition in the cortex has reached a given level, then it follows from the theory briefly stated above that extraverts and hysterics, who by hypothesis form inhibition potential more quickly and more strongly, would require less of the depressant drug to reach this point than would introverts. The experimental design would therefore require us in the first place to select two matched groups of extraverts and introverts respectively, and to study their behaviour with respect to our objective measure after the injection of varying amounts of, say, Sodium Amytal. Our prediction would be verified if the extraverted group required less Sodium Amytal to reach the critical point than did the introverted group. Details regarding the actual results of the experiment will be given below; it has merely been quoted here as an illustration of what, to us, appears a very powerful and useful experimental design which has unfortunately been very much neglected in the experimental literature. The importance of this type of design will be realized when it is recalled that individual differences in drug reactions are truly enormous, and may even give rise to apparently contradictory effects. By relegating them to an error term we make it very much more difficult for ourselves to find significant evidence for drug effects, and we also make it more difficult to duplicate findings in this field. When it is realized, in addition, that the relationship between dosage and drug effect may be curvilinear rather than monotonic, it will be clear that the neglect of personality factors implied in the first of the two methods discussed here carries with it a considerable waste of information. The failure of workers in the field to use the second method appears due largely to the absence of clearly formulated hypotheses relating drug effects to personality.

The Dimensional Analysis of Drug Effects

In spite of the great changes in psychological theory which have occurred during the past fifty years, the same tests appear to be used over and over again by psychologists. Reaction-time, continuous work curves, word association and time estimation were among the tests used by Kraepelin in his studies of alcohol, paraldehyde, chloral, morphine, etc. Other tests

which have survived for a long time are the ergograph, the dynamometer, and tests involving tapping and steadiness (Hollingworth, 1912). Some of the assumptions made by early workers regarding psychological functions measured by such tests as these have been abandoned, but new ones have taken their place for which also no good rationale can be detected. This is a point which has such far-reaching consequences, and is so important in the design of adequate experiments in the field of psychopharmacology, that a brief discussion of modern views of psychological testing appears to be in order.

Tests which are multifactorial (i.e. the performance of which is determined by more than one ability or personality trait) cannot give results permitting of any direct psychological interpretation. This can easily be shown by writing the typical factorial equation for the variance of any particular test A —

$$\sigma_A^2 = \sigma_a^2 + \sigma_b^2 + \sigma_c^2 + \dots + \sigma_n^2 + \sigma_s^2 + \sigma_e^2$$

According to this equation, the variance of performance scores on test A is made up of the additive variance of abilities (or traits) a, b, c, \dots, n , the specific variance (s) and the error variance (e). If we take a test such as the Complex Co-ordination Test (A), we find that performance on it is determined by the following factors: psychomotor co-ordination (a), rate of arm movement (b), spatial relations (c), perceptual speed (d), visualization (e), mechanical experience (f), numerical facility (g), and psychomotor speed (h) (Fleishman and Hempel, 1954). It will be clear that any change in performance after drug administration may be due to a change in any one, or in any combination, of these factors, and that it is impossible to assign the change in performance to any of these more fundamental psychological variables.

The position, in fact, is even more complex because the factorial composition of a given task does not remain constant during practice but changes markedly. As an example, we may quote another study by Fleishman and Hempel (1955). In Fig. 17.2 is shown the factorial composition of the Discrimination Reaction-time test at different stages of practice. It will be seen, for instance, that the factor "spatial relations" plays a far more important role in the factorial composition of test performance at the beginning than at the end of practice; the same is true of the "verbal" factor. On the other hand, "rate of movement" and "reaction-time" are factors accounting for a larger proportion of the variance towards the end of practice than at the beginning. Similar changes are indicated in Fig. 17.3, which is taken from Fleishman (1956); this demonstrates changes in proportion of variance contributed by each factor at successive stages of practice on a pursuit rotor test.

FIG. 17.2. FACTORIAL COMPOSITION OF DISCRIMINATION REACTION-TIME TEST AT DIFFERENT STAGES OF PRACTICE

(From Fletshman and Hempel, 1955)

These considerations, which have not to our knowledge been discussed previously in this connexion, suggest quite clearly that the only approach to drug studies which can give us psychologically meaningful information is the factorial, or dimensional, approach. Instead of using single tests of a multifactorial kind, it is suggested that batteries of tests defining meaningful and experimentally demonstrated psychological factors should be employed. This would do away with arbitrary and inconclusive test results and would link drug experiments more closely to the main body of psychological knowledge. If the points here raised are as vital as we believe them to be, then we must conclude that practically all the work that has been done in the drug field is only suggestive and does not enable us to derive any firm conclusions, because it has not, in fact, been undertaken from the dimensional point of view here advocated.¹

These considerations have a bearing on another point which we would like to stress. Much of the work summarized in this chapter has been done on the "blunderbuss" principle. A variety of tests, chosen more or less at random, or in terms of ease of administration, are given to a random group of subjects after the administration of a haphazardly chosen drug in the hope that interesting and important consequences may follow. The result of this type of approach has been disastrous. Little, if anything, is known with any degree of certainty about the psychological effects of drugs, and contradictory results are to be found on all sides. We venture to suggest that here, as elsewhere, worth-while results are more likely to follow upon clear-cut and specific theories which are stated in a sufficiently rigorous manner to make possible deductions which can be tested. If it be agreed that this is not an unreasonable proposal, then it would seem to follow that the most likely hypotheses

to be testable at the present moment would be hypotheses of a dimensional character. One such hypothesis has already been mentioned, namely, that relating depressant and stimulant drugs respectively to the extraversion-introversion dimension. Other dimensional hypotheses will suggest themselves to the reader as he goes through this chapter, which has been arranged in part to summarize the evidence regarding the influence of drugs on the three major personality dimensions dealt with in this book. Thus, adrenaline

FIG. 17.3. CHANGES IN PROPORTION OF VARIANCE CONTRIBUTED BY EACH FACTOR AT SUCCESSIVE STAGES OF PRACTICE ON PURSUIT ROTOR TEST
(From Fleishman, 1956)

¹ The same point may be made from slightly different premises. Learning theorists are agreed that performance is the product of several factors, such as drive (D), habit (sH_R), reactive inhibition (I_R), conditioned inhibition (sI_R), and so forth. If we consider for a moment Jones's (1958) modification of Hull's equation:

$$sH_R = (D + I_R) \times (sH_R + sI_R),$$

then we can see that the task score (sE_R) is determined by four variables, so that modifications in sE_R produced by drugs may be due to the effect of the drug on any one, or on any combination, of these four variables. Again, therefore, any direct interpretation of the results is plainly inadmissible; what is required is a specifically designed experiment to explore these complexities.

In this connexion also, unfortunately, it must be said that hardly any of the work carried out in the field of psychopharmacology is very illuminating or has had regard to these theoretical considerations. Occasional exceptions to these general strictures will be noted (see also Chapter 12 of this HANDBOOK by Franks) and there are some signs that work currently going on in psychological laboratories, at least, is based on a more sophisticated view of methodological requirements. The same cannot be said of work done in psychiatric laboratories, to which even the most elementary knowledge of learning theory does not seem to have percolated.

may be considered to be relevant to the dimension of neuroticism in the sense of increasing the emotional instability which is so characteristic of this factor. Conversely, sympatholytic drugs and some of the barbiturates would appear to have the opposite effect to adrenaline in the sense of decreasing the emotional over-response characteristic of neuroticism. Hallucinogens like LSD would appear to be related to the psychoticism dimension in the sense of increasing the thought disorders characteristic of this factor, while some, at least, of the so-called tranquillizers would appear to have the opposite effect. Hypotheses such as these, crude and over-simplified as they undoubtedly are, have one great advantage over most of the theories which we have encountered in this field. They are sufficiently clear-cut to be capable of being disproved experimentally because they give rise to rigorous deductions which do not admit of any ambiguity. It appears to us that hypotheses of this nature, even though they may turn out to be erroneous, are more fruitful in the long run than are more cautious, complex, and highly interpretive hypotheses which cannot be disproved experimentally because it is impossible to make any deductions from them which can be put to the experimental test.

This does not mean, of course, that the hypotheses

outlined above do not require certain qualifications. In the first place drugs tend to have multiple effects, and consequently it is by no means impossible that a drug exerts effects on two or all three dimensions, even though its main effect will be on one. This is not necessarily a disadvantage, nor does it make the dimensional analysis inapplicable. What we have to do, clearly, in the case of each drug is to relate it to all three dimensions and write its specification in terms of its direction cosines. (Such a procedure might have to be repeated with different dosages of the same drug in view of the fact that effects are occasionally curvilinear.) Such a set of specifications would tell us a great deal more about the psychological effects of a given drug than could be determined by any other method which is available at the present time.

Another complication which arises is due to the relatively arbitrary way in which drugs are grouped at the moment. Many quite divergent types of drugs are included under the heading "depressant" or "stimulant," and neither on pharmacological nor psychological lines can any of the present groupings be really justified. While this is true, it does not argue against the approach we suggest; quite on the contrary. It would appear that it is only by adopting whole-heartedly such a psychological method of grouping drugs along dimensional lines that we can hope to proceed further and to arrive at an appropriate biochemical and pharmacological analysis of those factors which underly uniform behavioural reactions. It may, moreover, be hypothesized that drugs whose actions are similar in terms of, say, direction cosines, will also be similar with respect to certain biochemical features which should be subject to analysis and which would make it possible to produce drugs which have some specific and precise action. Such an advance would also make possible a more rigorous determination of the site of action of the drug and thus would link up with the attempt to localize the physiological factors determining behavioural reactions concerning the three main dimensions of personality.

The factor-analytic approach suggested is probably the most generally useful when we are dealing with a dimensional problem such as the one which is now under consideration. Under certain circumstances, however, this method is faced with difficulties which suggest that an alternative should be looked for. The assumptions underlying factor-analytic work are so stringent on the mathematical side that it is sometimes doubtful whether the model is really a very suitable one for research into the relationship between drug effects and abnormal personality. It may be fruitful, then, to consider the possibility of a mathematical model which is known as *canonical*

variate analysis. Here the assumptions are less stringent and the model has particular advantages when diagnostic groups are to be used to identify the latent roots (Eysenck, 1957).

Let us consider a hypothetical experiment in which we seek to study certain hypotheses regarding the effects of Meprobamate on extraversion, neuroticism and psychoticism. We would select four groups of subjects, i.e. normals, psychotics, hysterics and dysthymics. Each of these groups would then be divided into two subgroups on a random basis, one of these two subgroups being given a *placebo*, the other Meprobamate. Subjects in all four groups would then be administered a battery of (say) ten tests which are known from previous work to be good measures of the three dimensions under investigation. Canonical variate analysis of the test scores of members of the eight groups (four diagnostic groups \times two drugs) would give us three, or possibly four, significant latent roots, which after suitable rotation could be identified in terms of our three dimensions, and, if a fourth dimension was called for, as a typical drug effect dimension external to the three dimensional model. Whether or not such a fourth dimension could be found, the position of the eight groups within the three-dimensional framework would tell us (a) whether the drug had a general effect along one or more of these dimensions and (b) whether this effect was, or was not, equal for different portions of the continua in question. Such a design would overcome the obvious difficulties which are involved in calculating correlations over diagnostic groups which could not be hypothesized to give rise to a normal distribution of scores along the various continua. A modified form of such an experiment has been reported by Eysenck and Eysenck (to be published); it illustrates the uses of this method in some detail.

It seemed worth while to discuss the possibilities of the dimensional approach in some detail because the data summarized below tend on the whole to support the kind of hypothesis which was outlined earlier in the section, and because without such a theory, which produces some kind of order in this vast field, the reader would be left with nothing but a whole series of independent, unintegrated and unassimilable research findings of doubtful reliability and having little meaning.

Having discussed in some detail the methodology of drug research, and some of the difficulties attaching to any worth-while study in this field, we shall now turn to a brief consideration of the experimental literature. We shall begin by discussing stimulants and depressants, pass on to the autonomic drugs and finish up with the hallucinogens and tranquilizers.

STIMULANTS AND DEPRESSANTS

Stimulants and depressants are both very heterogeneous groups of drugs. Little purpose would be served here by attempting to define the terms; instead the major drugs in each category will be listed and some of their complexities and paradoxical effects on behaviour described.

The drugs usually classed as *depressants*, according to Goodman and Gilman (1955) are—

1. *General anaesthetics*, such as ether and cyclopropane.
2. *Sedatives-hypnotics-soporifics*, such as *barbiturates*, chloral hydrate, and bromides.
3. *Antiepileptics*, such as diphenylhydantoin, phenobarbital, and trimethadione.
- ✓ 4. *Narcotics*, such as morphine, meperidine, and methadone.
5. *Analgesics and antipyretics*, such as salicylates and aminopyrine.
6. Centrally acting *skeletal muscle relaxants*, such as mephenesin and trihexyphenidyl.

These categories overlap considerably and even within the same category there are marked differences in the effects additional to the main depressant actions, which may themselves differ.

Moreover, even chemically similar compounds may have radically different effects; for instance, there are stimulant as well as depressant barbiturates, and Meratran, which is a stimulant, is an isomer of Frenquel which, in spite of its identical chemical composition (and only a slight difference in structure), antagonizes stimulants (Brown, Feldman and Braun, 1955) and is classed as an ataractic drug, or tranquilizer (Fabing and Hawkins, 1955).

Among the central nervous *stimulants* the diversity is even greater. Here, besides the differences in the mode and site of action there is apt to be a multiplicity of side effects: "In this respect they are in marked contrast to the central depressant drugs, which, for the most part, have a selective action on the nervous system" (Goodman and Gilman, 1955). Nevertheless, depressants are far from being homogeneous, although there has been no lack of theories attempting to explain their effects in terms of a single mechanism. Toman (1952) wrote: "So diverse in chemical structure are the many substances which produce central depression or complete anaesthesia that it is hard to imagine any single mechanism of action common to all. Indeed, there is no reason to believe that a common action is essential, since there must be as many different ways of blocking central nervous activity as there are independent parameters necessary for the normal maintenance of function in the central nervous system."

Although many substances will, in toxic doses, cause central stimulation, only a few are of clinical importance. They can be arbitrarily listed as follows—

1. The *analeptics*, such as picrotoxin, nikethamide (Coramine), pentylenetetrazol (Metrazol) and strychnine. They have been chiefly used to lessen narcosis and to stimulate respiration.
2. The *xanthines*, such as caffeine and theophylline (which is present in tea).
3. Certain *sympathomimetic* substances—
 - (a) The amphetamines.
 - (b) Cocaine.
4. *Miscellaneous stimulants*, such as Meratran and Ritalin. These do not appear to be related to any of the above-mentioned compounds, nor to each other, and having only recently been introduced, their usefulness has yet to be established.

Various other drugs which act principally on the autonomic system have some central stimulant action, e.g. atropine, ephedrine, nicotine, etc.

Although stimulants and depressants have actions which are opposed in some respects, the antagonism is usually not perfect, because each drug tends to have not just one effect but a whole range of effects, which are unlikely to correspond exactly with those of the antagonist. Some effects of stimulants and depressants are even synergistic (e.g. the effects of amphetamine and amylobarbitone on mood).

Some drugs which stimulate the nervous system in small doses cause depression if larger doses are given, and depression commonly follows the stimulant effect. The effects of certain drugs are apt to be unpredictable; for example, scopolamine in therapeutic doses is usually a depressant (except on respiration, which it stimulates), but it may occasionally produce excitement, restlessness, hallucinations and delirium (Goodman and Gilman, 1955). It cannot therefore be simply classified as a stimulant or as a depressant. Likewise, "It is undecided whether marihuana is primarily a central stimulant or depressant, or both" (Goodman and Gilman, *The Pharmacological Basis of Therapeutics*, p. 171).

It is clear that few, if any, drugs are *merely* stimulant or depressant, and that most occupy some position intermediate between these two extremes, that sometimes they are inconsistent in their actions and they have a variable range of side effects. The status even of well established stimulants and depressants has been doubted. For example, Heath (1954) considers that "it is highly questionable whether amphetamine actually stimulates" and according to

Toman (1952) amphetamine appears to be primarily depressant in its action on the sciatic nerve of the frog. Gottlieb (1951) put forward the view that amylobarbitone had a stimulant effect on the central nervous system which was normally masked by the hypnotic effect. That such paradoxical effects should occur at this highly complex level is understandable when it is remembered that even at the reflex level, stimulation of the vagus may cause the stomach to relax or contract, depending on the initial state of contraction, as Gerard pointed out in the *Symposium on Sedative and Hypnotic Drugs*, p. 104 (1954). The explanation given by Heath (op. cit., pp. 103-4), is that improvement through taking sedative drugs can only happen when there is already some degree of impairment because of internal stress: "Under these circumstances, through lowering the level of activity of the total organism the stress is likewise reduced so that it no longer has the same degree of incapacitating effect or inhibition. The end result then is performance at a slightly higher level than before the administration of the drug. Here, however, the individual cannot approach what is his theoretical maximal performance."

Domino, Fox and Brody (1955), who investigated the effects of a stimulant barbiturate, point out in this context the difficulties in classifying the actions of barbiturates into stimulants and depressants on the basis of "gross observations." "The usual definition of a 'stimulant' is an agent that increases a functional activity, and that of a 'depressant' as an agent that decreases functional activity. In the complex organization of the central nervous system it is difficult to determine whether a compound is a true 'stimulant' or 'depressant' on the basis of gross observations in the intact animal. A drug may exert its effects at a variety of central sites. It may act at the neuronal level either to excite or depress; it may act at the synapse or other portions of the neuronal arc, or it may influence facilitatory or inhibitory neurons which feed into the common nervous pathway. Thus a pharmacological agent that stimulates inhibitory neurons might be an overt depressant, whereas an agent that selectively depresses inhibitory neurons may cause an overt excitatory response."

Thus, even in neurophysiology there are difficulties in ascertaining whether an agent should be classed as a stimulant or depressant, and further difficulties arise as these terms are so often used in a wider sense, e.g. to describe overt behaviour, but as Wikler (1950) points out: "The use of terminology borrowed from pharmacology or neurophysiology such as 'stimulation,' 'depression,' 'facilitation' and 'inhibition' to describe phenomena concerned with total adaptive behaviour is not only unjustified, but actually misleading." (See also Wikler, 1952.)

There has been much emphasis lately on the effects of drugs on the reticular activating system, and correspondingly less emphasis on Hughlings Jackson's concept of levels (e.g. Elkes, Elkes and Bradley, 1954). The importance of this system was only discovered recently, having escaped attention because the earlier experiments on the electrical activity of the nervous system had been done with the animals under general rather than local anaesthesia (Magoun, 1954). It is variously described as the mesodiencephalic activating system, the midbrain reticular formation of Moruzzi and Magoun and the thalamic diffuse projection system of Jasper. (See *Symposium on Brain Mechanisms and Consciousness*, edited by Delafresnaye, 1954.) If this region is stimulated electrically in a sleeping animal, arousal occurs with the characteristic EEG changes (i.e. desynchronization with disappearance of the large slow waves and spindle bursts characteristic of sleep). Its destruction in monkeys makes the animals appear as if asleep or deeply anaesthetized. The ascending reticular activating system is a multi-neuronal afferent pathway concerned with the general alertness of the animal, in contrast to the specific nature of the classical sensory pathways.

This system appears to be very sensitive to depressant drugs, such as Nembutal (pentobarbitone sodium) and ether: "Activity evoked in this subcortical mechanism by afferent stimulation shows a markedly greater susceptibility to alteration by drugs and metabolic changes than does concomitant discharge conducted to sensory areas of the cortex in direct afferent paths." (Arduini and Arduini, 1954, who confirmed the findings of French, Verzeano and Magoun, 1953.) This differential sensitivity is surprising as it has usually been assumed that the cortex was more metabolically active than the lower parts of the central nervous system and that the sensitivity was directly proportional to the metabolic activity (e.g. Himwich, 1951, 1955). It is, however, likely that the complexity of internal organization of the reticular system is at least as great as that in the cortex and that the intricacy of synaptic connexions is "of greater importance in determining sensitivity both to pharmacologic agents and to metabolic alterations than is the anatomical position of the part in a Jacksonian schema of serial horizontal levels." (Arduini and Arduini, 1954.)

Stimulants such as amphetamine (Elkes, Elkes and Bradley, 1954) or strychnine and Metrazol (Arduini and Arduini, 1954), increase the responsiveness of the reticular activating system. Thus, it appears that although stimulants and depressants have widespread effects, "their influence on the subcortical arousal mechanism may account in considerable measure for their generalized effects." (op. cit.)

Unfortunately the drugs usually classed as

stimulants and depressants are not the only ones which affect this system. Rinaldi and Himwich (1955a) suggest that this is the "specific site of action" of atropine and of cholinergic drugs, acetyl-choline producing the alerting reaction and atropine inhibiting it. There is evidence that, in therapeutic doses, chlorpromazine has a "suppressive action on the 'upward discharge' of the ascending reticular formation" (Das, Dasgupta and Werner, 1954), whereas therapeutic doses of reserpine apparently stimulate the mesodiencephalic activating system (Rinaldi and Himwich, 1955b). These two drugs are described as "tranquillizers" rather than as depressants because, unlike the latter, they may induce a calm state without any concomitant confusion, and if sleep occurs it is of moderate depth and the patient can easily be aroused from it. Nevertheless, they have, potentially, the effects of certain depressants. There still remains much work to be done before the different effects of these substances on the activities of the various parts of the brain are elucidated.

According to Eysenck's theory (1957) "extraverted behaviour patterns are produced by excessively strong reactive inhibition and/or excessively weak excitation, while introverted behaviour patterns are produced by excessively weak reactive inhibition and/or excessively strong excitation." He further postulates that depressant drugs increase cortical inhibition, decrease cortical excitation and thereby produce extraverted behaviour patterns, whereas stimulant drugs decrease cortical inhibition, increase cortical excitation and thereby produce introverted behaviour patterns. The evidence for this theory will be discussed later but it is worth pointing out here a possible connexion between the hypothesized (molar) basis of extraversion-introversion and the mesodiencephalic activating system. If stimulants and depressants have any common denominator this system appears to be the most likely but, at best, an action on the reticular activating system is a necessary and not a sufficient condition for stimulation or depression. It is conceivable that the reticular activating system is more active or more responsive in introverts than in extraverts. If this were the case, it would follow that any drug which increased the activity of this system would tend to be introverting, and conversely. But this is probably an oversimplification, as drugs have numerous different sites of action, and similarly, it would be surprising if the basis for a fundamental difference in personality were located in a precise region of the central nervous system.

This development of Eysenck's theory has a certain plausibility; it avoids the confusion which arises as soon as the terms "stimulant" and "depressant" are introduced, and is consistent with some of the features characteristic of introverts and extraverts. It

can be fairly¹ easily tested by studying the relationship between the effect of drugs on the reticular activating system and performance (under the influence of the drug) on the tests and questionnaires which are used to define extraversion-introversion operationally. In the course of the review any instances for and against this theory and its tentative extension will be noted. It follows from the latter that a variety of drugs, not classed as stimulants or depressants, should affect extraversion-introversion. For example, reserpine should be introverting and likewise cholinergic drugs, whereas atropine should be extraverting.²

The Amphetamines

Although amphetamine was introduced into clinical medicine only just over twenty years ago (Prinzmetal and Bloomberg, 1935), there is already an extensive psychological literature devoted to it and the related compounds. (Amphetamine itself is a volatile liquid which was used in nasal inhaler tubes until the dangers of consuming the contents (about 325 mg) were pointed out (e.g. Monroe and Drell, 1947). It is usually administered orally in the form of its sulphate.) Up to 1940, most of the work was on the racemic amphetamine sulphate (Benzedrine, Mecodrine, and Isomyn being some of the equivalent names). The dextro-rotary isomer, dextro-amphetamine sulphate (*d*-amphetamine or Dexedrine) is now more commonly used, as its central effects are supposed to be relatively stronger than those of amphetamine. A related and rather similar compound is methylamphetamine (Methedrine or Pervitin, or desoxyephedrine). Chemically they resemble adrenaline and ephedrine. The drug is sympathomimetic and raises the blood-pressure. The usual oral dose for an adult is 5-20 mg of amphetamine sulphate or 2.5-10 mg of *d*-amphetamine sulphate. Absorption is rapid and, although effects may be noticed about twenty minutes later (Seifert, 1939) they do not reach their maximum until 1-2½ hours later. Their action is prolonged, and a dose after 3 p.m. may interfere with sleep.)

Among the conditions for which the amphetamines are prescribed are narcolepsy and obesity, as these

¹ This qualification is necessary, because other factors may influence the response to the drug, e.g. social factors. For example, a large dose of a moderately quick acting barbiturate may make the subject "happy, hilarious and drunk" or "gloomy, moody, depressed, weepy," according to the way the situation is manipulated.

² Since this view was put forward by Dr. Trouton, it has become apparent that there may be two parts of the reticular activating system: (1) an adrenaline-sensitive portion which, when stimulated produces arousal; (2) an acetylcholine-sensitive portion which, though it gives rise to EEG changes characteristic of sleep and wakefulness, does not produce the behavioural counterparts. The brain stem arousal mechanism thus appears to be truly *adrenergic* (Rothballer, 1956, 1957): hence prediction concerning the possible relationships of parasympathetic drugs and introversion-extraversion might not turn out to be as postulated.

drugs tend to increase alertness and to decrease appetite. (For further uses see Bett *et al.*, 1955.) In psychiatry they are given intravenously for abreactive treatment (e.g. Jonas, 1954), as an aid to psychotherapy (e.g. Schilder, 1938; Agoston, 1944) or for diagnostic purposes (e.g. Delay *et al.*, 1948; Simon and Taube, 1946).

Although intravenous amphetamine to some extent reverses barbiturate anaesthesia (Myerson *et al.*, 1939; Jacobsen *et al.*, 1938), the antagonism is by no means perfect, and the Newmans (1956) concluded that *d*-amphetamine "in ordinary therapeutic doses were ineffective in combating the depressant effect of alcohol" (see also Bovet and Bovet-Nitti, 1948; Koppányi and Fazekas, 1950, and Nickerson, 1950). In some respects, the amphetamines and barbiturates are synergistic and they are commonly prescribed together orally as Drinamyl or Dexytal, or intravenously in the belief that the effects on mood are enhanced and the peripheral effects minimized; they may also be given together, intravenously (Gottlieb, 1949; Delay, 1949; Gottlieb *et al.*, 1952; Houston, 1952; Reznikoff, 1941; Davidoff *et al.*, 1941). Tolerance, habituation and addiction may all occur, the incidence of the last being assessed differently according to the way that addiction is defined; this is in contrast to the barbiturates which "are addicting drugs no matter how the word addicting is defined" (Isbell and Fraser, 1950). Since amphetamine is chemically related to certain hallucinogens and, like them, tends to inhibit synaptic transmission (Marrazzi and Hart, 1955b), it is not surprising that prolonged and excessive administration of it may produce a schizophrenic-like state. (For description of amphetamine craving, addiction and psychosis, see Norman and Shea, 1945; Wallis *et al.*, 1949; also Freyham, 1949; Knapp, 1952; Hermann and Nagler, 1954; Chapman, 1954; Connell, 1956a and b.) The early work on amphetamine was reviewed by Ivy and Goetzl (1943); a more recent review, dealing with the neurological and psychiatric aspects of these drugs, is that by Bonhoff and Lewranz (1954).

CLINICAL OBSERVATIONS

After studying the reactions of over two hundred subjects to amphetamine sulphate, Reifenstein and Davidoff (1939) characterized the actions of the drug as "variable, uncertain, unpredictable and at times paradoxical." Their table provides a convenient summary of the main effects (Table XVII.2). The "paradoxical" effects are most likely to occur with large doses. This table includes most of the symptoms which have been observed after the administration of amphetamine to normal subjects (e.g. Gwynn and Yater, 1937; Nathanson, 1937; Bahnson *et al.*, 1938), and some of the toxic effects noted by Wand (1938).

TABLE XVII.2

EFFECTS OF AMPHETAMINE SULPHATE

(1) STIMULATION OF MENTAL RESPONSE

(a) *Major effects.* Acceleration of the stream of mental activity and increase in content of thought; increase in co-ordinate mental activity and general efficiency; increase in perception and alertness; increase in initiative; increase in attention and meticulousness; decrease in confusion; decrease in sleep requirement and insomnia; decrease in fatigue; decrease in reticence and improved performance on psychometric tests.

(b) *Paradoxical effects.* Retardation of the stream of mental activity; incapability to concentrate; forgetfulness; dullness; increase in fatigue, malaise and drowsiness; decrease in perception and alertness; decrease in attention; confusion; transitory delirium; tactile and other somatic hallucinations, paraesthesias and anaesthesias, heart consciousness, and generalized sensations of warmth.

(2) STIMULATION OF SPEECH FUNCTION

(a) *Major effects.* Increase in speech activity, disappearance of mutism, talkativeness to the point of loquaciousness; increase in accessibility with willingness to discuss personal problems, ventilation of conflicts, and elaboration of delusions and hallucinations; and increase in coherent and relevant speech.

(b) *Paradoxical effects.* Decrease in speech activity, decrease in logical progression of thought with increase in incoherent and irrelevant speech.

(3) STIMULATION OF MOTOR FUNCTIONS

(a) *Major effects.* Increase in motor activity; increase in co-ordinate physical activity with increase in physical efficiency; tremulousness, restlessness, extreme hyperkinesia; and aggravation of convulsive seizures.

(b) *Paradoxical effects.* Decrease in motor activity with decrease in physical efficiency.

(4) STIMULATION OF AFFECTIVE FUNCTION

(a) *Major effects.* Elevation of mood with cheerfulness, a feeling of well-being, exhilaration, euphoria, elation; uncontrollable laughter; facetiousness; a state of ready irritability and increased irritation; increase in drive, urge and spontaneity; decrease in shyness; increase in confidence; hair-trigger-like reactions with sudden changeability of mood; agitation, impatience, impulsiveness, and self-assertiveness approaching aggressiveness in some; aggravation of assaultiveness, and homicidal tendencies in mentally ill persons.

(b) *Paradoxical effects.* Lowering of mood with depression or melancholy; uncontrollable crying; aggravation of suicidal tendencies; resentfulness; surliness; anxiety; and increase in worry.

The reports of the effects of the amphetamines in different psychiatric disorders are somewhat conflicting. "The literature on Pervitin has consistently revealed that this drug may either relieve or exacerbate the same abnormal mental state." Normal subjects are said to be more affected by these drugs than are psychotics (Davidoff, 1936; Davidoff and Reifenstein, 1937), but even psychotics with the same diagnosis may be affected in diametrically opposite ways. For example, Delay (1949) found that catatonia was aggravated, whereas Hope, Callaway and Sands

(1951) found that catatonic patients were improved by 20 mg methylamphetamine intravenously. Acute schizophrenics were more responsive than the chronic ($N = 30$). Delusions and abnormal thought processes were accentuated or made more accessible. A similar effect on delusions had been observed by Levine, Rinkel and Greenblatt (1948), who compared the psychological and physiological effects of intravenous methylamphetamine, amphetamine and amylobarbitone sodium. Pennes (1954) also compared the first and last of these three drugs, together with mescaline, on fifty-five schizophrenics; he found that whereas the barbiturate was predominantly normalizing and the hallucinogen intensified the symptoms, methylamphetamine tended to produce an unstable state, with either normalization or intensification of symptoms. However, Schube *et al.* (1937) found that none of a group of eighty psychiatric patients were benefited by amphetamine and Wootley (1938) found that half of his group of seventy psychiatric patients were unaffected by amphetamine, even in large doses. Wilbut *et al.* (1937), Cameron and Kasanin (1941), Rudolph (1949), Monro and Conitzer (1950), Rudolph (1956), found little of value in the application of the drug to neurotics.

Certain types of psychopath, particularly those with a persistent theta rhythm in their EEG, tolerate the drug well and respond favourably to it. According to Hill (1947): "The personalities which respond are those showing an aggressive bad-tempered and generally hostile tendency in interpersonal relationships, which is manifested whenever frustration is met." He also states that the schizoid or paranoid personality does not respond: "The patient must be capable of some warmth and capable of emotional attachment."

The effects of amphetamine do not appear to be related to sympathotonia or vagotonia (Wootley, 1938) nor to body build (Jacobsen and Wollstein, 1939). Bett (1946) asserted: "People of pyknic build appear to tolerate it better than the asthenic. The former react with a more parasympathetic type of response . . . while the latter respond more sympathetically with palpitations and tremors. Depending on the predominance of one or other type of response, the effect of Benzedrine will be mainly beneficial or mainly unpleasant." This sounds plausible, but is not in accordance with the experiments quoted above.

Recently von Felsinger, Lasagna and Beecher (1955) have attempted to correlate the personality and the reaction to drugs in twenty healthy young male volunteers. The psychological data were based on an interview (and the inevitable Rorschach). Changes in mood and behaviour were assessed by questionnaires and by direct observation through a one-way window. The predominant reaction to amphetamine 20 mg per

70 kg bodyweight was euphoria,¹ but four experienced dysphoria, and five felt sedated. The seven subjects who showed marked stimulation were the "most responsive and expansive" and well-adjusted, whereas those responding with dysphoria were conspicuously lacking appropriate motivation in their work, and were the heaviest consumers of alcohol (being "suspected of having neurotic causes for their drinking"). Marked depressive trends and moodiness were among the "undesirable" characteristics of those who were sedated by amphetamine.

Each subject was tested on four other occasions, when he received an injection of *placebo*, heroin, morphine or pentobarbitone. The general conclusion was—

The atypical responses were most frequent in the least balanced persons. It is not unreasonable to assume that such a personality structure, already inadequate to deal with everyday stresses, fraught with impulsivity and anxiety, and fearing loss of control, may be alarmed by the surge of stimulation and energy associated with amphetamine . . . A well balanced personality structure, on the other hand, could conceivably integrate such stimulation into outgoing activity without disturbance and with pleasant effect.

They interpreted the sedative effect as a "defensive reaction."

PSYCHOLOGICAL EXPERIMENTS

The most ambitious of the researches on the psychological effects of amphetamine was carried out by Carl and Turner (1939; also Turner and Carl, 1939; and Carl and Turner, 1940). They used a large battery of tests on four groups (each of about thirty-five subjects), who were tested twice, first without any drug and subsequently after a (1) *placebo*, or after (2) 10, (3) 20, or (4) 30 mg amphetamine. Testing was begun 75–90 min after administration of the drug. (Groups (3) and (4) received 10 mg of the dose during the session.) It is not clear how the subjects were allotted to the groups, but those under twenty-one tended to be placed in the *placebo* group (Turner and Carl, 1939).

The performances at the first session and early and late in the second session were compared on nearly forty different items. Some of their more definite findings are referred to subsequently but few of the intergroup differences are beyond the "realm of only very moderate statistical probability." Altogether the reports of their studies occupy about two hundred pages, but their cautious and critical interpretation leaves little which can be justifiably abstracted from

¹ Turner and Carl (1939) found evidence of a change from depression to elation, using an Optimism-Pessimism scale, and also a more favourable attitude towards work. The changes in the Bernreuter scale were inconsistent, but in the direction of "lowered introversion (higher extraversion), increased dominance, heightened self-confidence and greater sociability."

its context. The ratio of words to definite statements is rather high.

EFFECTS ON INTELLIGENCE TEST PERFORMANCE AND REASONING

In terms of Furneaux's (1952) analysis of intelligence (cf. Chapter 5 by W. D. Furneaux) it would be theoretically possible that amphetamine might influence the *speed* or the *level* (the latter being partly dependent upon persistence). No statistically significant improvement in score on intelligence tests appears to have been reported, although some increase was found in several of the studies (e.g. Molitch and Sullivan, 1937, *see also* Sargant and Blackburn, 1936; Peoples and Guttman, 1936; Bradley, 1937; McNamara and Miller, 1937; Wollstein, 1939;

Bradley and Green, 1940; Cutler *et al.*, 1940; Golla *et al.*, 1940). The studies by Carl and Turner (1939) are inconclusive. Neither schizophrenics (Broadhurst, 1957) nor mental defectives (Morris *et al.*, 1955) do better on intelligence tests when given an amphetamine.

It is possible that the same dose of amphetamine may improve the performance of some subjects, and impair that of others. This view was put forward by Hecht and Sargent (1941) who tested three groups of about thirty subjects each on a reasoning test and on a disarranged words test before and after receiving 10 mg amphetamine sulphate, a *placebo* or no drug. The variability was great, and none of the differences between the groups were significant. Similarly, Andrews (1940) found no statistically significant increase in scores on tests of syllogistic reasoning.

TABLE XVII.3
THE EFFECTS OF THE AMPHETAMINES ON ASSOCIATIVE TESTS

A. Arithmetic Tests		
Author	Test or function	Effect
Peoples and Guttman (1936) McNamara and Miller (1937) Bradley (1937)	Continuous addition (Kraepelin) Multiplication of pairs of 3-digit numbers Arithmetic tests in children	Increase in speed No appreciable effect on speed or accuracy No improvement in non-fatigued subjects working at their best
Barmack (1938)	Adding 6-place numbers	More problems attempted and accuracy unaffected Subjects less bored
Flory and Gilbert (1943) Kleemeier and Kleemeier (1947)	Continuous addition Complex multiplication (a) Cancellation of incorrect answers to simple multiplication problems (b) Arithmetic speed test	No improvement in non-fatigued subjects working at their best ¹ 15 mg amphetamine may impair performance (a) Marked and statistically significant increase (b) Some increase
Duker and Duker (1953)	Continuous addition and subtraction	Improvement in speed and accuracy ¹
B. Other Associative and Psychomotor Tasks		
Author	Test or function	Effect
Kleemeier and Kleemeier (1947)	(a) Letter cancellation (b) Paper and pencil motor tests (c) Word completion	Differences not significant but means higher in subgroups receiving amphetamine
Carl and Turner (1939)	Taylor number test (connecting numbers in order) Word production test (cf. (c) above) Imagination test	Improvement, although not demonstrated in a "thoroughly reliable manner" Improved by moderate doses; also by large doses in some, whereas others became confused
Wunderle (1941) Welch <i>et al.</i> (1946)	Tapping test (cf. (b) above) Association of ideas Association to low association nonsense syllables	Slight improvement, especially in accuracy Increased ¹ Significantly greater in normal subjects if 10 mg <i>d</i> -amphetamine given one hour before (but increase not comparable with that found in elated patients)

¹ Methylamphetamine was used in these experiments.

EFFECTS ON ASSOCIATIVE FUNCTIONS

These are summarized in Table XVII.3. The administration of an amphetamine may lead to a statistically significant improvement in certain associative tasks. This is clearly demonstrated in Kleemeier and Kleemeier's (1947) carefully controlled experiments (see Table XVII.3 A and B). In these, twenty-seven students were tested at sessions held at weekly intervals, receiving a glucose *placebo* or 10 mg amphetamine sulphate, according to the following scheme—

Session	1	2	3
Group A	practice	glucose	amphetamine
Group B	practice	amphetamine	glucose
Session		4	5
Group A		glucose	amphetamine
Group B		amphetamine	glucose

The capsules were administered ninety minutes before the beginning of the sessions, which lasted for two hours. The data were combined from sessions 2, 3, 4 and 5 to give each individual a total amphetamine score and a total *placebo* score for each test. "By combining the data in this way, practice effects were

subject was required to mark correct answers or specific letters, while in another part he was required to mark wrong answers and letter groups containing none of the previously specified letters. "The latter is a considerably more difficult task," and there was a tendency for such tasks to be facilitated by amphetamine.

The discrepancies in Table XVII.3 are probably mostly explicable as a result of differences in dosage, length of work period and practice effect. Too large a dose may impair performance (e.g. Carl and Turner, 1939; Flory and Gilbert, 1943). The effects of the drug become more marked towards the end of the session, as Barmack (1938) found; he attributed the discrepancy between his findings and those of McNamara and Miller (1937) to the fact that his subjects had been required to work for ten times as long as theirs. The fact that the problems set by McNamara and Miller were more difficult than those set by Barmack or by Kleemeier and Kleemeier, and that their experimental design may have resulted in the drug effect being obscured by the practice effect, also probably contributed to their failure to find a significant improvement.

TABLE XVII.4
THE EFFECTS OF AMPHETAMINES ON LEARNING IN MAN

Author	Test	Result
Carl and Turner (1939)	Learning "Z" digit-symbol substitution (adapted from Morgenthau and Healy-Bronner)	Improved by moderate doses of amphetamine; high doses produced improvement in some and deterioration in others
Carl and Turner (1939)	Learning "D" (Healy-Bronner picture-paragraph memory test)	Little affected
Kleemeier and Kleemeier (1947)	Selective substitution test (cf. Learning "Z" test above)	Significant improvement
Lemmel and Hartwig (1940)	Nonsense syllable learning	Improved
Willet (1957)	Nonsense syllable learning (by serial anticipation method)	Improvement, but not statistically significant

cancelled out, and equating of groups as to initial ability was unnecessary."

Their experiments cannot be described further here, but two of their findings may be of general interest. Firstly, they found no evidence that fast and slow workers were differentially affected by amphetamine. Secondly, they found evidence that the drug increased flexibility of performance or "the ability to break through 'set'," "set" being defined as "the predisposition to respond in a particular way." Most of the tests had been devised so that the mental set had to be changed several times during the course of any single one of them. For example, in the part of the Letter Series and of the Multiplication Test, the

EFFECTS ON LEARNING

In Man

Most of the work with the amphetamines has been concerned with the effects on performance rather than on learning and the data on the latter from human studies are scanty. The unsatisfactory evidence summarized in Table XVII.4 indicates that some improvement in learning may occur, but the most recent and the most adequate study of serial anticipation learning of nonsense syllables (Willet, 1957) did not show that the drug (10 mg *d*-amphetamine) led to a statistically significant improvement, nor were anticipatory errors increased. The serial position effect was likewise

unaltered, an unexpected finding in view of the role which has been attributed to reactive inhibition (I_R). There was, however, a statistically significant decrease in the area between the curves of first success and last failure, and similarly a decrease in the number of fluctuations at the threshold of recall. As part of the same study, Franks and Trouton (1957) studied the effects of various drugs on the conditioned eyeblink response; subjects who had received *d*-amphetamine sulphate before acquired the responses more rapidly and lost them more slowly than those who had received a *placebo* or amylobarbitone sodium.

In Animals

There is evidence that conditioned reflexes in both rats and dogs are enhanced by amphetamine (Wentink, 1938; Alpern *et al.*, 1943; Skinner and Heron, 1937).

Minkowski (1939) found that rats learnt a maze less readily under the influence of the drug, but the drive used was hunger, and it is well known that amphetamine reduces appetite. More recently Ewing *et al.* (1952) used thirst as the drive and found that whether the rats were injected with an amphetamine (e.g. 1 mg/kg *d*-amphetamine) or saline: "All groups reached a point of maximum proficiency with minimum errors on the seventh trial. . . . Thus there is no evidence that this treatment had any influence on maze-learning ability." Larger doses resulted in impairment. Ewing *et al.*, however, admit that they "have not eliminated the possibility that there might be a proper small dose that would increase the ability of rats to learn the maze."

EFFECTS ON ROTE MEMORY

Amphetamine does not appear to improve digit span or rote memory (Carl and Turner, 1939; Wunderle, 1941).

EFFECTS ON "ATTENTION" AND VIGILANCE TESTS

The various tests of "attention" probably measure different functions, but they are dealt with here for convenience. Barmack and Seitz (1940) found no evidence that the drug increased the "span of attention" for letters, but there was a marked practice effect. Lemmel and Hartwig (1940) found that amphetamine or methylamphetamine enabled subjects to reproduce correctly more drawings which had been exposed tachistoscopically; they claimed that there was less evidence of rational distortion but more of emotional distortion in subjects under the influence of the drug.

Mackworth (1948) reported the effects of 10 mg amphetamine sulphate on the performance of a task requiring sustained attention. In the Clock test of visual vigilance, a response is made as quickly as possible on each occasion that a clock hand gives a

double jump instead of a single one. The reaction-time to these double jumps increases sharply after half an hour of watching. This increase could be prevented either by supplying the subjects with a continuous knowledge of the results of the test, or by supplying them with amphetamine. "It is clear that when Benzedrine was given, not only were the subjects able to detect more signals, but they were slightly quicker at responding to the signals they did notice." (1948, p. 43.) "There was no sign, however, that this Benzedrine level of efficiency was any better than the normal optimum without Benzedrine" (op. cit., p. 32). Incidentally, no "hangover" effects from the drug (10 mg) were observed; the control run score taken the day after a Benzedrine day was no worse than that taken the day after a control run (op. cit., p. 33).

SENSORY AND PERCEPTUAL FUNCTIONS

There appears to have been little work done on the effects of amphetamines on sensory functions, and, therefore, the findings reported here are rather miscellaneous.

The decrease in flicker fusion threshold towards the end of the day can be more than counteracted by amphetamine (Simonson *et al.*, 1941). Roback *et al.* (1952) claimed that the increase in threshold was proportional to the dosage of *d*-amphetamine. Numerous other studies have shown a similar effect with amphetamine (or a decrease of F.F.T. with depressant), e.g. Landis and Zubin (1951), Seashore and Ivy (1953). (For a review of F.F.T., see Simonson and Brozek, 1952, and for an annotated bibliography, Landis, 1953.)

Yudkin (1941) found a transient increase in dark adaptation.

Wunderle (1941) found that subjects tended to underestimate the length of periods of time under the influence of methylamphetamine, in accordance with Turner and Carl's (1939) finding with amphetamine. The rate of fluctuation of a Necker cube did not differ significantly as a result of administration of *d*-amphetamine, a *placebo* or amylobarbitone sodium (Eysenck, Holland and Trouton, 1957b).

REACTION-TIME

Although Lemmel and Hartwig failed to find any effect on reaction-time, Thornton *et al.* (1939) found that amphetamine had a more marked effect than caffeine on the shortening of reaction-time. The drug affects the decrements produced by prolonged vigilance (Mackworth, 1948).

EFFECTS ON MOTOR FUNCTIONS

General Activity and Speed

Using the revolving cage method, Searle and Brown (1939) found that a 3 mg/kg dose of amphetamine

produced a greater increase in the activity of rats than either a 1.5 mg/kg or a 4.5 mg/kg dose. This illustrates one of the problems encountered in research with this group of drugs as, owing to wide individual variations, it is impossible to predict the optimal dose. Tainter (1943) also found a marked increase in activity with amphetamine, although caffeine had little effect. Chance (1947) reported that curious social behaviour occurred in rats after large doses, but the validity of his findings has been questioned (Ross *et al.*, 1951, and Gunn and Gurd, 1940).

Although an increase in general activity has often been observed in man clinically, this does not appear to have been quantified in relation to dosage. However, Golla *et al.* (1940) timed various familiar performances by subjects, without their knowledge. Both methylamphetamine and amphetamine increased the speed with which the majority of subjects signed their name, and similarly the speed of walking across a room and throwing darts. In the "overt" test, speed of drawing was increased, and also "speed of decision" as measured by the time taken in choosing a column of figures to add.

EFFECTS ON MOTOR TASKS

Skilled Tasks

The effects of the amphetamines on certain skilled tasks are summarized in Table XVII.5. Unless the

sional Pursuit Test. In this the subject is required "to correct for the random drift of four simulated aircraft instruments from their null positions by the timely and appropriate manipulation of four simulated aircraft controls. A timer is activated only when all four instruments are concurrently maintained in their null positions. A cycling system meters out alternate work trials (one minute) and rest periods (fifteen seconds) for any desired span of time" (Hauty and Payne, 1955). The apparatus resembles the controls of an aeroplane, but not as closely as does the Cambridge Cockpit; performance on it has a correlation of 0.3 with basic flying proficiency.

In most of the studies of work decrement, a preliminary practice period is given (fifty minutes), then a rest (ten minutes), followed by a final work period of four hours or more. "Under normal operating conditions nearly all subjects exhibit significant decrement during the first two hours of the final period" (Payne and Hauty, 1955). Various factors influencing the level of performance and its rate of decrement have been studied. Dextroamphetamine sulphate is the most effective agent for preventing or counteracting the work decrement (Fig. 17.4). The role of the drug was considered to be "that of protecting a normally progressing learning function against the cumulative burden of such factors as attitudes of aversion, boredom, physical discomfort and possibly the physiological fatigue of sensorimotor

TABLE XVII.5
THE EFFECTS OF AMPHETAMINES ON SKILLED MOTOR TASKS

Author	Test	Result
Barmack (1939)	Poffenberger pursuit meter by practised subjects for two hours	15 mg amphetamine sulphate retarded the development of inaccuracy and also "retarded the development of a condition leading to a report of boredom. . . ."
Davis (1948)	Cambridge cockpit	With doses of 10, 15 and 20 mg amphetamine: "No effects were observed in the majority of cases." (The drug tended to reduce deterioration through lack of sleep, but otherwise did not reduce errors.)
Payne and Hauty (1953, 1955a, 1955b)	USAF SAM Multidimensional pursuit test	<i>d</i> -amphetamine is the most effective agent for counteracting work decrement (<i>see text</i>)
Eysenck, Casey and Trouton (1957)	Pursuit rotor	<i>d</i> -amphetamine increased performance as compared with the <i>placebo</i> group, this effect becoming more marked as the experiment proceeded

task is prolonged, or the subject suffering from lack of sleep, there is little effect.

Several large-scale experiments, mostly utilizing a factorial design have been carried out recently by Payne (1953) and Payne and Hauty (1953, 1954, 1955), Payne and Moore (1955), and Hauty and Payne (1954, 1955), mostly utilizing the USAF SAM Multidimen-

systems" (op. cit.). However, there was some evidence that the effects of the stimulant could not be ascribed to "concomitant euphoric changes in task attitudes." That is to say, "an indoctrination designed to solicit the most favourable attitudes towards the task at hand" failed to alter the rate of decrement of performance although it did improve the feelings and

attitudes (Payne and Hauty, 1953). By a combination of "conditions involving specific cue feed-back, motivation feed-back, and cerebral stimulation" a striking improvement in performance can be brought about (Payne and Hauty, 1955c).

Relatively Unskilled Tasks

Ergograph. The amphetamines can delay work decrement on various types of ergograph (Lehmann *et al.*, 1939; Alles and Fergen, 1942; Knoefel, 1943;

FIG. 17.4. EFFECTS OF PHARMACOLOGICAL TREATMENTS UPON TASK PERFORMANCE
(From Payne and Hauty, 1955)

Cuthbertson and Knox, 1947) and can help to counteract a moderate degree of deterioration. However, if the subject has worked to a state of exhaustion, e.g. on a bicycle ergometer until no longer able to maintain the needle on the dial in a position corresponding to 54 r.p.m., intravenous injection of amphetamine (10–15 mg) or methylamphetamine (5 mg) does not increase the rate of recovery, whereas injection of 0.5 G caffeine sodium benzoate does (Foltz *et al.*, 1943). Moreover Lehmann *et al.* (1939) considered that the drug was likely to be dangerous in heavy workers because it might lead to the "consumption of the functional reserves which the organism retains as protection against too extensive exhaustion."

Steadiness. Most of the tests of steadiness have required that the subject should place a stylus into a series of apertures of graded sizes, the number of contacts in a given period being electrically recorded. The methods used have varied and the results have been rather conflicting. The topic has recently been illuminated by the discovery that steadiness is not unitary. This conclusion is based on two very different types of evidence, factor analysis and high speed photography. Hauty (1954), who has investigated the effects of drugs on hand steadiness, describes two different components: (1) a large slow tremor involving "the co-ordinative activities of those per-

ceptual and musculature systems which determine the precision of manual movements in arriving at a fixed point in space and either maintaining this point or moving to successive fixed points. . . . Its initiation and conduct is dependent upon the integrative functions at the cortical level." Superimposed on this is (2) a fine rapid tremor "resulting from the imbalanced state of neuromuscular activity and, contrary to earlier concept, is considered as being causally dissociated from cortical activity."

There being evidence that amplitude and frequency of tremor are inversely related, it was argued that in the stylus and graded aperture type of apparatus "the score obtained at the smallest aperture of the apparatus to be used should consist, therefore, of a considerable if not predominant proportion of [fine] tremor movements," whereas the coarser "co-ordinative activities component" would be derived from the scores on the larger apertures.

Sixty-six subjects were first given three practice trials (each trial consisted of having to insert the stylus in turn into the six graded apertures and to maintain it there for thirty seconds). The score for each aperture was recorded separately. The subjects were then randomly assigned to one of six groups, receiving (a) 5 mg and (b) 10 mg dextroamphetamine sulphate; (c) 100 mg and (d) 200 mg quinalbarbitone (Seconal); (e) a placebo, (f) no drug. They were tested at hourly intervals. It was found that the barbiturate reduced the fine tremor but adversely affected the co-ordinative activities, whereas dextroamphetamine increased the fine tremor but did not significantly affect the latter. Doubling the dose of stimulant had no significant effect, but the larger dose of depressant led to a further significant reduction in the fine tremor and also to an increase in the coarse tremor. The placebo group showed significantly greater tremor ($p < 0.05$) than the group which did not receive any drug, presumably a manifestation of apprehension.

Tapping. Tapping tests usually measure not only the speed (maximal or preferred) of movement, but also varying amounts of dexterity and co-ordination. If the test is prolonged, fatigue or reactive inhibition is a further factor which is involved.

Simonson and Enzer (1941) claimed that the rapidity of pressing a button was a measure of the "maximum frequency of motor impulses," and showed that this was increased by the administration of amphetamine. Carl and Turner (1939) used a dotting test and found there was an improvement, especially in accuracy, with small doses of amphetamine, but large doses had a deleterious effect. Thornton, Holck and Smith (1939) using a test involving tapping alternately on two adjacent copper plates for three different periods, as well as tests of

reaction-time, handgrip and steadiness, found that the subjects made better average scores on the days when they received amphetamine. Only three subjects were used but they had eight practice sessions followed by over twenty experimental sessions each, during which the effects of amphetamine were compared with those of caffeine and a *placebo*. Cranston, Zubin and Landis (1952) also included a tapping test in their battery,

1947; Tyler, 1947) but not necessarily the performance (e.g. Foltz *et al.*, 1943a; Somerville, 1946), except in lengthy or boring tests (e.g. Tyler, 1947), especially those requiring sustained alertness (e.g. Seashore and Ivy, 1953; Mackworth, 1948). Unpleasant subjective effects appear to be less common in those who are fatigued (Alwall, 1943), although various psychological disturbances may occur, even

TABLE XVII.6
THE EFFECTS OF AMPHETAMINES IN PROLONGED EXERCISE

Author	Study	Result
Alwall (1943)	700 soldiers doing hard exercises for 3 nights and the intervening days, with little sleep	(a) 20 or 30 mg amphetamine or (b) 18 mg methylamphetamine mostly gave a more favourable response than the <i>placebo</i> and with no more side effects. (b) was <i>not</i> twice as potent as (a).
Foltz <i>et al.</i> (1943)	23 untrained subjects with heavy knapsacks on their backs had to step up and down on to a stand every 3 sec until fatigued. Tested after (a) 10 mg amphetamine (b) 0.5 G caffeine (c) <i>placebo</i>	No significant differences between (a), (b) and (c) but practice effect was marked. "It is evident, then, that training had a much greater effect on performance than did the drugs."
Somerville (1948)	50 soldiers and 73 officers during prolonged operations	Even 40 mg amphetamine had little effect.
Cuthbertson and Knox (1947)	Two companies of an infantry battalion, on 48-hour operations. One receiving amphetamine, the other <i>placebo</i>	70 per cent receiving the drug thought that it diminished fatigue, compared with 23 per cent in control group
Tyler (1947)	20 controlled experiments on volunteers from the Services, deprived of sleep for 24–112 hours and required to do heavy activity. Barbiturates or amphetamines given in small doses. Battery of tests administered each evening	"In general where a psychomotor test was of relatively short duration . . . no significant changes in performance occurred even after 110 hours wakefulness."
Seashore and Ivy (1953)	Several experiments on soldiers after prolonged work or marching. Tests of speed and precision, tremor, sway and co-ordination, etc.	<i>Placebos</i> —little effect. Caffeine—improved subjective reports but motor performance little improved. Effects more marked with the amphetamines

but analysis of variance failed to reveal any statistically significant effects of the various drugs used.¹

EFFECTS ON MARCHING, PROLONGED WAKEFULNESS, ETC.

The full evidence concerning the usefulness of the amphetamines in military operations has presumably not been made public and the evidence that is available is conflicting (*see* Table XVII.6). From the work of the authors quoted here it appears probable that: amphetamines have beneficial effects chiefly in those who have been deprived of sleep, improving the attitude to the task² (e.g. Cuthbertson and Knox,

psychotic episodes resembling "acute schizophrenia," which were observed by Tyler (1947) in some of those who had received the *placebo*, and not amphetamine. Undesirable side effects were noted by Cuthbertson and Knox (1947), and Russell Davis (1947, 1948) has pointed out the risk of causing impairment of judgement in those who are driving cars or aeroplanes.

SUMMARY AND CONCLUSIONS

Some of Carl and Turner's conclusions (1939) remain valid—

1. "Moderate (10 mg) dosage of Benzedrine produces a tendency toward accelerated reaction in psychomotor output, so long as the execution of the actual physical movements does not require thinking or deliberation. Heavy dosage (10 mg added to 20 mg) seemingly produces a retardation in these functions

¹ Factor analysis was also used in this study, but their procedure is difficult to justify.

² Tyler (1947) found that a small dose of a drug, such as amphetamine, markedly decreased the proportion of men deciding to discontinue the experiment.

at a point following ingestion by about thirty minutes—a retardation which persists for another forty minutes.

2. "Accuracy in most of the tests seems to be relatively unaffected by doses of ordinary size (10 mg), even though speed increases."

3. The tasks most favourably affected by the amphetamines are those which are prolonged and boring, the effect of the drug tending to prevent or counteract the work decrement or loss of alertness, and becoming relatively more pronounced as the work is continued.

4. The drug usually produces a more favourable attitude towards the task, but this does not necessarily correlate with improvement.

5. Associative functions (e.g. association to non-sense syllables, continuous addition, etc.) are more liable to be improved than cognitive functions such as intelligence, or learning.

6. Individual variations are considerable, and it is possible that a given dose can have opposite effects on the same activities in different subjects.

7. The relation between the response to amphetamine and personality has not been elucidated, nor has it been established whether there are qualitative differences between the various amphetamines in their psychological effects.

In Hullian terms, the amphetamines appear both to increase drive (D) and to decrease reactive inhibition (I_R), any improvement in initial performance being largely attributable to the former and any improvement during a prolonged task being attributable to the latter effect.

Caffeine and other Stimulants

Caffeine (1,3,7-trimethylxanthine) is a central stimulant contained in several drinks such as cocoa and maté, as well as tea and coffee. In some of these dimethylxanthine, theobromine and theophylline, are also present; their properties are somewhat similar and they are all diuretics. They tend to relax smooth muscle but to improve the contraction of voluntary muscle by a direct local action in addition to their central effect. There is also a direct local action on the blood vessels and heart, which tends to be antagonistic to the effects produced by stimulation of the medulla. It is therefore difficult to predict the total effects of the drug on, for example, blood-pressure, which may remain unchanged in spite of changes in the circulating system.

Caffeine is usually administered orally or intravenously in the form of its soluble double salt, caffeine and sodium benzoate, the dosage being gr 2–10 (120–600 mg). A cup or two of tea or coffee is said to contain about 150–250 mg caffeine. Absorption is rapid and "appreciable blood levels persist for six to twelve hours" (Goodman and Gilman, 1955). Habitua-

tion and tolerance may occur, and chronic poisoning, with insomnia and restlessness, has been described.

As most of the work on the psychological effects of caffeine dates from before 1940 and is included in earlier reviews, it will only be briefly presented.

The early studies on the effects of caffeine on fatigue by Hoch, Kraepelin, Mosso and many others about sixty years ago are described by Rivers (1908), whose own experiments confirmed "in general, the conclusion reached by all previous workers—that caffeine stimulates the capacity for muscular work; and it is clear that this increase is not due to the various psychical factors of interest, sensory stimulation, and suggestion which the experiments were specially designed to exclude" (cf. Foltz *et al.*, 1942). He considered the chief interest of his experiments was the "clear demonstration of the very different way in which the same doses of the drug may act on different persons." It is also of interest that his earlier experiments were conducted without the use of *placebos*, but this deficiency was soon remedied.

Hollingworth's work, sponsored by the Coca-Cola Company, has been largely confirmed subsequently. (See Table XVII.7.) "One of the most interesting facts shown by these experiments is the complete absence of any traces of secondary depression or of any sort of secondary reaction consequent upon the stimulation which is so strikingly present in many of the tests" (Hollingworth, 1912a). As with the amphetamines, the relation between dosage and effect is not always linear, too large a dose usually resulting in impairment. The main effects are shown in Tables XVII.7 and XVII.8. The finding by Hollingworth (1912) that small doses of caffeine tended to result in retardation of the discrimination reaction-time, whereas larger doses increased the speed of reaction appears inconsistent with the effects on, for example, co-ordination which was improved by small doses and impaired by larger doses of caffeine. The explanation given by Hollingworth was that small amounts of caffeine resulted in increased briskness and an increased liability to false reactions, and that the retardation was due to caution in trying to avoid these (cf. Thornton *et al.*, 1939).

There is evidence that caffeine improves conditioning, but Lashley (1917) found that caffeine retarded the learning of a circular maze by rats. Tolman (1917) carried out a series of experiments in which gr $1\frac{1}{2}$ of caffeine or a *placebo* were administered on alternate days two and a half to three hours before the subjects learned nonsense syllables. He found that there was less reactive inhibition engendered in learning the relatively pleasant lists and that the number of consonants learned was greater for the caffeine than for the non-caffeine groups. Clark Hull (1935) returned to this problem. In his controlled experiments, gr 5 of

caffeine were given to eight males three and a half hours before learning a list of sixteen syllables. With caffeine there were more anticipatory displacements, but there was a mean reduction in rate of learning, amounting to 2-3 per cent (although this was not statistically reliable). The gaps in the tables reveal

Other Stimulants

Other stimulants include cocaine which, being unsuitable for psychological experimentation, will be omitted,¹ and two recently introduced drugs. One is benzhydrol, *x*-(2-piperidyl) benzhydrol hydrochloride or Meratran, which is isomeric with Frenquel, a

TABLE XVII.7
MAIN STUDIES ON PSYCHOLOGICAL EFFECTS OF CAFFEINE

Author	Main details of experiments	Results
Hollingworth (1912)	16 subjects were tested over a period of 40 days with and without caffeine. Tests included— 1. Tapping 2. Steadiness 3. Co-ordination (3 hole test of combined accuracy and speed) 4. Typewriting (by one subject) 5. Colour naming } 6. Opposites } 7. Calculation } 8. Discrimination reaction times	Effects of caffeine— Improvement. Tremor. Improvement with small doses and retardation with large. Speed increased by 1-3 gr and decreased by 4-6 gr but errors decreased by both. All improved. "Small amounts . . . tend to produce retardation. . . . Larger amounts . . . produce within 2 hours after the dose a stimulation so great that retardation following small doses does not appear."
Gilliland and Nelson (1939)	5 subjects given 12 practice periods on a battery of tests, before being tested 20, 100 and 140 min after coffee or a decaffeinated beverage was given. Pulse, tapping, reaction-time Adding, memory span Steadiness (Bryan tracing board)	Results equivocal. Effects of caffeine were most marked during second testing period All significantly decreased
Barmack (1940)	Adding 29 subjects under different conditions for 8 15-min periods	Increased, but not consistently Decreased.
Cheney (1936)	10 subjects practised for a week on pressing the key corresponding to any one of three coloured lights, testing being carried out every half hour during the mornings. Comparisons between final normal day when subject received water, the coffee day, the caffeine day and final control day (water and starch capsule)	Caffeine had a negligible effect on initial rate of addition, regardless of the time of its administration, but exerted a beneficial effect when alertness would otherwise have become blunted Reaction-time decreased only if the dosage of caffeine exceeded 3 mg/kg body weight. No effect found after 24 hours. (Statistical methods not used.)
Stanley and Schlosberg (1953)	Carefully designed experiment to assess effects on (a) Simple and (b) Complex reaction-times	Decrease in both (a) and (b) immediately after drinking tea in habitual tea-drinkers Steadiness most affected.

how unsystematically the psychological effects of caffeine have been studied. Owing to differences in tests used, some caution is necessary in attempting to compare the effects of caffeine with those of amphetamine, but it appears that the effects of small doses of caffeine are usually less marked and less consistent than those of a small dose of amphetamine.

tranquillizer (Fabling and Hawkins, 1955). The other is Ritalin or phenyl-(*x*-piperidyl)-acetic acid methyl ester. Both are supposed not to be sympathomimetic.

¹ Strychnine has also been studied, but no effects on Hollingworth's tests were apparent. (Poffenberger, 1914.) However, Lashley (1917) found that large doses of strychnine produced improvement in both learning and performance of a maze by rats.

Little experimental psychological work has been done on either. Drassdo and Schmidt (1954) found some evidence that Ritalin tended to counteract the effects of a barbiturate on arithmetic. Kleemeier, Rich and Justiss (1955) investigated the effects of

Meratran on the performance of senile patients on tests of visual perception, sorting, tapping, verbal output, time estimation, figure drawing and hand strength. Each patient was tested weekly, twice with the drug and twice without. "Although there was a

TABLE XVII.8
A COMPARISON OF THE PSYCHOLOGICAL EFFECTS OF CAFFEINE AND AMPHETAMINE

Author	Findings on caffeine	Findings on amphetamine (see section on amphetamine for references)
<i>Cognitive functions</i>		
Cattell (1930)	Intelligence and Reasoning (see Jellinek and McFarland, 1940)	Slight but insignificant increase. No improvement.
Lashley (1917)	Learning (conditioning improved as with amphetamine) Caffeine retarded the learning of a circular maze by rats	Maze learning retarded except by small doses.
Tolman (1917)	Nonsense syllable learning. Less retroactive inhibition, and number of consonants learned was greater after caffeine than after a placebo	Slight but non-significant improvement.
Hull (1935)	Nonsense syllable learning. More anticipatory displacements after caffeine and a slight mean reduction in rate of learning	Slight but non-significant improvement in learning. No increase in anticipatory errors.
<i>Associative functions and psychomotor tests</i>		
Hollingworth (1912)	Colour naming improved Opposites test improved Typewriting (1 subject)—increase in speed with small doses, decrease with large	— — —
	Calculation test—increase in speed with small doses, decrease with large. Cancellation test—equivocal	(See below)
Gilliland and Nelson (1939)	Memory span improved Rate of adding improved (neither consistently)	Probably improved. No evidence of improvement. May be some improvement in simple calculation such as continuous adding but the discrepancy between the placebo and the drug performances becomes greater as the task is more prolonged.
Barmack (1940)	Adding not improved initially, but only when alertness would have become blunted	
<i>Reaction-time (= R.T.)</i>		
Hollingworth (1912)	Discrimination R.T. retarded by small doses, stimulated by large.	
Gilliland and Nelson (1939)	Simple auditory R.T. significantly decreased	
Cheney (1935, 1936)	Discrimination R.T. (pressing keys to coloured lights). R.T. decreased only if caffeine > 3 mg/kg body weight	
Stanley and Schlosberg (1958)	Immediate decrease in both simple and complex R.T. after drinking tea in habitual tea-drinkers	
Thornton <i>et al.</i> (1939)	Effects on R.T. not significant	
<i>Motor functions</i>		
Rivers (1908) (reviewing work of Hoch, Kraepelin, Mosso and others, and quoting his own)	Improves capacity for muscular work, e.g. on ergograph	Amphetamines apparently less effective in increasing rate of recovery if practised subjects have worked to exhaustion on a bicycle ergograph.
Foltz <i>et al.</i> (1943)	Confirmed the above, used more refined techniques. Co-ordination test improved with small doses, retarded with large	Co-ordination may be improved if impaired by lack of sleep.
Hollingworth 1912	Tapping improved. Steadiness decreased	
Gilliland and Nelson (1939)	Tapping significantly decreased. Steadiness decreased	
Thornton <i>et al.</i> (1939)	Handgrip strengthened. Steadiness decreased	Amphetamine slightly more effective. Steadiness increased.

general tendency for increases in amount of production on the tests under the experimental condition, in only figure drawing, hand strength and time estimation did the group performance under the drug condition seem to be significantly altered."

One further study is of interest because it was specifically designed to test Eysenck's (1957) theory of drug action. Sinha (1957), using response alternation in rats as his measure of reactive inhibition, employed Meratran as the stimulant drug, amytal as the depressant drug, as well as a *placebo*, all drugs being administered in difference sequence to the sixty-four animals making up the experimental population. The apparatus used was a simple T maze with food always present at both ends of the maze. Runways were attached to the stem of the maze in such a way that, depending on the point of the maze where they were started, rats were required to make one, two, or three right or left turns before reaching the choice-point of the T. It was predicted (1) that the greater the number of turns in any given direction preceding the choice-point, the greater would be the tendency of the rats to turn the other way at the choice-point. On the hypothesis that this tendency was due to reactive inhibition and that reactive inhibition was increased by amytal and decreased by Meratran, it was predicted (2) that the animals' tendency to turn in the direction *opposite* to that which had been forced upon them by the maze before reaching the choice-point would be *strengthened* by amytal and *reduced* by Meratran. Fig. 17.5 shows the results of this experiment, and it will be seen that the prediction is borne out by the experimental results.

The Barbiturates

In the half century since the first barbiturate was introduced, these drugs have largely displaced the other hypnotic drugs. Chemically they are derivatives of barbituric acid, which is the product of the condensation of malonic acid and urea. Over 2,500 derivatives have been prepared by substituting various radicals for the hydrogen atoms, which has provided an opportunity to correlate the chemical structure with the pharmacological effects, but little work has been done on the differences between the psychological effects of the various compounds.

The drugs are classified according to their duration of action, e.g. (1) long-, (2) intermediate-, (3) short- and (4) ultra short-acting (Goodman and Gilman, 1955, p. 138).

Examples of these different classes are (1) phenobarbitone, (2) amylobarbitone (amytal) (3) pentobarbitone (Nembutal) and quinalbarbitone (Seconal), and (4) thiopentone (Pentothal). Terminology is confusing as even the official nomenclatures of the U.S.P. and B.P. differ, the former preferring

endings in "-al," instead of the British "-one." As sodium amylobarbitone happens to have been used more extensively than its competitors in the studies reported here the descriptions will chiefly apply to this drug. It is also known as "amobarbital sodium" U.S.P. and "Sodium Amytal" (Lilly) and should not be confused with amylobarbitone ("amytal") of which

FIG 17.5. ALTERNATION SCORES AFTER 0, 1, 2, OR 3 PREVIOUS TURNS AS AFFECTED BY DRUGS
(From Sinha, 1957)

it is the sodium salt; the effects of amylobarbitone sodium¹ (sedative dose gr 1 orally, hypnotic dose gr 3-gr 9) appear fairly soon and are of medium duration, whereas those of amylobarbitone (sedative dose gr $\frac{1}{4}$ to gr $\frac{3}{4}$, hypnotic gr $1\frac{1}{2}$ to gr 3) are of medium onset and longer duration.

The main effect is, of course, depression of the central nervous system in degrees varying from mild sedation through sleep to anaesthesia. The cortex, hypothalamus and particularly the ascending reticular activating system (Magoun, 1954; Arduini and Arduini, 1954) appear to be the sites which are most sensitive to the effects of the drug.

Barbiturates do not have much effect on the pain threshold except in doses sufficient to impair consciousness (Wolff *et al.*, 1941). "It may be inferred . . . that whatever salutary effects may follow the administration of Sodium Amytal in painful conditions, they do not stem from the blocking of pain perception. They must occur either because of alterations in the reaction of the subject to the painful experience or from interruption of the mechanism responsible for

¹ Amylobarbitone sodium will be referred to as amytal.

the noxious stimulus" (Wolf and Ripley, 1948; *see also* Beecher, 1947; Wikler, 1950; Keats *et al.*, 1950).

Much work has been done on the EEG effects: "In general, the EEG records obtained under hypnotic doses of barbiturates in animals and man are similar to those of natural sleep" (Goodman and Gilman, 1955). Brazier and Finesinger (1945) investigated the effects of intravenous barbiturates on the EEGs of thirty-two patients. In all subjects the EEG record showed the development of high voltage fast activity. In those receiving larger doses per kg body weight a second effect developed; this consisted of slow delta waves (3-4 per sec). In every subject the high voltage fast activity appeared first in the frontal leads, then in the parietal and finally in the occipital, and disappeared in the reverse order (i.e. the phylogenetically most recent were the most vulnerable). In the first few minutes, at the stage of maximal action, the patient may be unconscious without the appearance of any of the brain waves typical of sleep. These may appear later, but on arousal there is a reversion to the high voltage fast activity which is specific for barbiturates. They considered that these results were compatible with the hypothesis that the drug had two effects: (1) interference with the dehydrogenase systems and (2) a change in the permeability of the cell membrane (*see also* Brazier, 1954).

The barbiturates have peripheral as well as central effects, chiefly on the autonomic nervous system. Amylobarbitone in anaesthetic doses has a parasympatholytic action, tending to block the vagal effects; it may also interfere with "the liberation of the adrenergic mediator into the blood stream" (Goodman and Gilman, *op. cit.*, p. 132). Hexobarbitone (Evipan) is also parasympatholytic (Emmeline, 1941) but Trewethie (1953) found that Nembutal (pentobarbitone sodium) had a blocking effect on the sympathetic nervous system peripherally. To what extent such effects contribute to the clinical diminution of anxiety is uncertain.

Not all barbiturates are depressants on anti-convulsants. For example, sodium 5-ethyl-5-(1,3-dimethyl-butyl) barbiturate has stimulant and convulsant properties. Gottlieb (1951) found that this drug tended to diminish depression and to cause euphoria. He also put forward the view that amytal has a stimulating action on the central nervous system, which is masked by the hypnotic effect when larger amounts are given and that this may be responsible for the euphorogenic effect. Pennes (1954) administered the drug to schizophrenics and found it to have a beneficial effect on symptoms but also to cause convulsions. The pharmacological effects were fully investigated by Domino *et al.* (1955) who found evidence of depressant effects in addition to the other properties.

The drugs may be given by mouth or by injection, the effects of oral administration of amytal becoming apparent in twenty to fifty minutes and of intravenous injection (e.g. of Pentothal) almost immediately. The drug soon becomes distributed to all tissues, fatty tissues being of especial importance in this connexion. The slower and longer acting compounds, such as barbitone, tend to be excreted in the urine, whereas the more rapidly acting compounds (e.g. those with branched sidechains) tend to be broken down in the liver.

The chief uses of the barbiturates, besides sedation and hypnosis, are for the control of epilepsy, for inducing anaesthesia, and, in psychiatry, for narco-analysis. Habituation, tolerance and addiction may occur (Isbell and Fraser, 1950; Tichy, 1953), and there is a well marked abstinence syndrome.

CLINICAL EFFECTS

Numerous articles have appeared on the clinical effects of barbiturates, and in particular of sodium amylobarbitone; most of them are purely descriptive.

Effects of Barbiturates on Mood, etc.

One of the first to investigate the effects of an intravenous barbiturate (amytal) on the mood of normal as well as of psychiatric subjects was Lindemann (1932, 1934; Lindemann and Malamud, 1934). He found that the drug tended to cause an increase in rapport and communicativeness and also an increased interest in the outer world. "Individual differences manifested themselves in talkativeness in one subject and more quiet serenity in other subjects." There was also a "shifting of the emotional state along the depression-elation scale in the direction of elation." Among the physiological effects noted were slurring of speech, mydriasis, a fall in blood-pressure and pulse rate and an increased pain threshold (but cf. above). In neurotic subjects there is usually a diminution of any anxiety present (Delay *et al.*, 1948a) and, with larger doses, abreaction sometimes occurs.

There also appear to be differences between the effects of different barbiturates. For example, Delay *et al.* (1948a) state that Pentothal is inferior to amytal in reducing anxiety. Wendt (1954) using an adjective check-list has found consistent differences between amytal and Seconal. "First, 200 mg of amobarbital causes the subjects to describe themselves in this way: *more*: drowsy, lightheaded, tired; *less*: cheerful, contented, co-operative, earnest, easygoing, energetic, enterprising, responsive, self-confident, and sympathetic. . . . Under Secobarbital, 100 mg they are *more*: amiable, courageous, decisive, elated, energetic, exultant, forceful, responsive; *less*: obedient, relaxed, quiet and satisfied." (In Wendt's studies which have been carried out in conjunction with Nowlis and

others the effects of the social situation have been carefully controlled.)

There is some evidence that amytal increases the degree of extraversion (as predicted by Eysenck's theory). Laverty and Franks (1956) found that there was a significant increase in the R score of Guilford's S.T.D.C.R. after amytal, but this may be attributable to the fact that the number of "yes" replies was increased by the drug.

Effects in Relation to Psychiatric Disorders

Freyhan (1952) after investigating over two hundred patients by means of narcoanalysis with amytal concluded: "There are no similar kinds of response and there are no clear relationships to specific kinds of personality disorder." Likewise Wolf and Ripley (1948) conclude after studies on seven hundred patients: "It is clear from these data that Sodium Amytal has no direct predictable effect on the mood and attitude of the subject." In neither of these researches, however, was any adequate assessment of personality made.

Use in Diagnosis

Hoch (1946) considered that barbiturates such as amytal were reliable diagnostic agents which deserved much more widespread use. Administered intravenously, they may be of value in differentiating between—

1. organic and functional psychiatric disorders
2. functional disorders and malingering (Ludwig, 1944; Ripley and Wolf, 1947)
3. psychoses and neuroses (e.g. between hysterical amnesia and aphonia and schizophrenic mutism) (Sullivan, 1942; Hoch and Polatin, 1949)
4. "borderline" schizophrenia and psychopathic personality (Donahue *et al.*, 1948)
5. manic and catatonic stupors (Berrington, 1939).

They may also aid in diagnosis when used in psychotherapy by enabling further information to be elicited (e.g. Wedge and Moulton, 1950) or in improving contact (Smith and Schwartz, 1934). Thorner (1935a) found that 42 per cent of 207 patients "expressed ideas not previously indicated." (He does not, however, state what were the proportions of the various diagnostic groups included.) Bellak (1949) found oral barbiturates useful in overcoming resistance in psychotherapy, and in helping the patient to free-associate; he explained this facilitation as due to a decrease in anxiety with a concomitant decrease in the need for repression.

This increase in talkativeness has led to the appellation "truth drug" being applied to the barbiturates. But there is no reason to suppose that what is said under these conditions is more likely to be true than

what is said in an undrugged state. The "memories" of episodes, such as alleged sexual traumata, recovered during psychoanalysis are often spurious. This is supposed not to detract from their value from the psychoanalytical point of view, but such memories are worthless from the legal point of view. It is likely that similar considerations apply to attempts at recalling past experiences after the injection of a barbiturate. Intravenous barbiturates may, of course, be of therapeutic or diagnostic value in criminals (Adatto, 1949) but Gerson and Victoroff (1948), who studied the validity of confessions obtained under the influence of a barbiturate, concluded that "there is no such thing as a 'truth serum'. . . . The validity of confessed material may be seriously limited by fantasies and delusions which are indistinguishable from truth." The chief indications appear to be for investigating cases of suspected malingering, loss of memory, and false avowals of guilt, or when great fear is present. An intravenous barbiturate, particularly if given in conjunction with an amphetamine, may also make an uncommunicative subject less cautious and more loquacious, but, to discover whether the utterances are true or false, some independent criterion is necessary.

Barbiturates and Brain Damage

The greater susceptibility to barbiturates of those with organic rather than functional psychiatric disorders was reported by Lorenze *et al.* (1934). Since then, various attempts have been made to use these drugs for detecting brain damage. It should be noted that this fact, if substantiated, would be in good agreement with Eysenck's theory (1957), as he posits increased inhibitory effects as a direct function of brain damage. (Cf. also Chapter 14 on brain damage.)

Berg (1949) gave hexobarbitone (Evipan) to normal subjects in 5, 10 and 20 per cent of the estimated narcotic dose and found that the flicker fusion threshold was unaltered; but, in patients having brain injuries, 10 per cent of the narcotic dose resulted in a decrease in flicker fusion.

Other tests have been based on the effects on the EEG: for example, Witter and Müller (1953) found a correlation between the severity of brain damage and the amount of increase of EEG activity after administration of Evipan (cf. Bergman *et al.*, 1953-4). The effects on the EEG in functional psychiatric disorders are discussed in the next section.

Weinstein and his colleagues claim that amytal is of value as a test of brain damage (Weinstein and Kahn, 1951; Weinstein *et al.*, 1953; Weinstein and Malitz, 1954; Weinstein *et al.*, 1954; and Kahn *et al.*, 1956). They found that in patients who had shown denial of illness and disorientation for time and had recovered, these phenomena could be reproduced by the

intravenous injection of amytal. They compared the responses (1953) of eighty-eight neurological patients having brain disease, caused by tumours, degenerative and demyelinating diseases, etc., with those of fifty patients who had peripheral nerve lesions or neuroses. They used a standard set of questions, concerning orientation and awareness of illness, before and after the injection of amytal. "A 2.5 per cent solution was injected intravenously at the rate of 0.05 G per minute. The subject was asked to count backwards from 100 to 1. At the point where nystagmus, errors in counting, dysarthria, and drowsiness were produced," the standard set of questions which had been asked immediately before the injection, was repeated (e.g. "What is your main trouble? How did it come about? Are you worried about it?" etc.) (Weinstein and Malitz, 1954). "Prior to receiving the drug, all patients expressed awareness of illness, were completely orientated for place, and identified the examiners correctly. With the drug, explicit denial of illness, disorientation for place, and gross misidentification of the examiners occurred only in some of the patients with brain damage. In the normal group, subjects talked of illness in terms of a third person, used more 'concrete' symbols, selectively misinterpreted questions about illness and misnamed the examiners in 'paraphrastic fashion.' These patients were not necessarily more communicative. Many showed no change. Some talked more, others talked less, and while some talked more, they communicated less information." The authors considered that the effects could not be adequately explained in terms of "cortical depression" or "release of repressions" or "inhibitions" (as, for example, Kubie and Margolin, 1945, postulated) but rather as an adaptive defence in a stressful situation, much of the behaviour being the manifestation of a particular observer-subject relationship. (For example, "the degree of ataxia varied greatly with the audience," and many of the defects were selective, patients being alert to some questions and giving inaudible replies to others.) However, such effects did not occur with injections of sterile water.

In a further study, Weinstein and Malitz (1954) investigated the effects of injections of amytal on a hundred general medical patients, half of them suffering from brain damage. In fifty-seven of the eighty-eight patients with brain disease who had shown no disturbances of behaviour on clinical examination, "the intravenous administration of the drug produced patterns of disorientation for time, place, and person, and denial of illness. These changes were not obtained in any of the fifty control patients."

Weinstein *et al.* (1954) found that the results of the amytal tests at different stages of the illnesses of thirty-four patients paralleled the improvement, and more recently Kahn *et al.* (1956) have found a "close

relationship between the short-term response to treatment [by E.C.T. administered to twenty-four patients] and the results of the amobarbital tests." Teng and Bender (1955) have found amytal of value in bringing out latent motor deficits due to lesions in the central nervous system. Weiner and Harlow (1952) found that in monkeys the more severe the brain damage, the greater impairment of learned performances when pentobarbitone sodium was administered.

The Sedation Threshold

Recently Shagass has developed a quantitative method using intravenous amytal for assessing manifest anxiety and tension in neurotics and the "degree of impairment of ego functioning" in psychotics (Shagass, 1954; Shagass and Naiman, 1955 and 1956; Shagass, Naiman and Mihalik, 1956; Shagass, 1956; Shagass, Mihalik and Jones, 1957). The measure obtained is termed the "sedation threshold"; this is "defined as that amount of sodium amytal (in mg per kg body weight) required to produce an inflection point in the amplitude curve of frontal 15 to 30 c/s activity, within one injection interval of onset of slurred speech. The inflexion point was defined as that point which followed an abrupt rise in the curve and preceded a tendency to flatten, or the point just preceding a clear plateau in the curve."

The procedure was for the patient to lie on a bed, while a continuous frontal EEG record was taken; 0.5 mg per kg body weight of amytal (in 1 c.c.) was injected at the beginning of every forty-second period. "Questioning was started after twenty-five seconds. The patient was asked how he felt and then asked to repeat numbers and words . . ." EEG changes similar to those observed by Brazier and Finesinger (described above) occurred. "The development of fast frequency potentials usually took place in a gradual manner. However, in most records there seemed to be a point at which relatively sudden increase in voltage and amount of frontal fast activity occurred, followed by relatively little increase thereafter. This transition point was found to coincide with the development of slurred speech . . ." (cf. Fig. 17.6).

The sedation threshold was highly and significantly correlated with the degree of "tension" as assessed psychiatrically in neurotics and in pseudoneurotic schizophrenics. Among the other schizophrenics, the correlation was not significant (Shagass, 1954) and it was considered that this was due to the influence of another factor, namely impairment of ego functioning. In a subsequent study Shagass and Naiman (1955) have produced evidence suggesting that impairment of ego functioning lowers the sedation threshold. They argued that "the chronic schizophrenic group would have higher thresholds than apparently equally tense patients with acute schizophrenia or agitated

depressions." This was shown to be the case. Among normal subjects "there was a higher positive correlation between the sedation threshold and the number of symptoms of manifest anxiety elicited in a psychiatric interview." There was also a significant relationship between the threshold and the score on a self-administered symptom inventory (Saslow Screening Test). Those with organic psychoses had the lowest thresholds.

In a further study (Shagass and Naiman, 1956) the sedation thresholds for one hundred and twenty-one neurotics and forty-five normal subjects were compared. The "mean threshold for the control subjects was 3.09 mg per kg which was significantly lower than the mean for the neurotics ($p < 0.001$). The mean threshold for the hysterics (twenty-six cases) was 2.88 and for anxiety states 5.38 (twenty-nine cases). The differences between the diagnostic categories are shown in Fig. 12.6 in Chapter 12, "Conditioning and Abnormal Behaviour," by C. Franks. The test-retest reliability is high, and the results little influenced by differences in age, sex and amounts of past sedation (but alcoholics and addicts were excluded). The technique is difficult, chiefly because of the need to avoid EEG artefacts during injection. Slurring of speech is only "an adequate indicator for extremely high or low thresholds," EEG control being needed for most of the intermediate ones.

The authors note the close agreement between their findings and the dimension of extraversion-introversion as independently established by Eysenck (1947). They write: "If one assumes some kind of personality continuum, with the hysteric at one extreme and the obsessional at the other, the sedation threshold probably gives a fairly accurate indication of the position of an individual on this continuum." This personality correlate of the sedation threshold should perhaps be emphasized as much as its correlation with manifest anxiety, since it provides a link with important experimental evidence obtained by other methods. In particular, they mention the striking fact that in Hildebrand's (1953) study using objective psychological tests of introversion-extraversion the order in which the various neuroses were arranged by the test scores was "remarkably similar to the order in which they were arranged by the sedation threshold." They suggest "that these various tests probably measure different aspects of the same basic central nervous function." According to Eysenck's theory (1955) this is reactive inhibition which was predicted to be more marked in extraverts (and hysterics) than in introverts (and dysthymics).

Sodium Amytal, being a depressant drug would be postulated to increase inhibition. An extravert, whose cortex, according to . . . [Eysenck's] . . . theory, is already in a relatively inhibited state, should require

comparatively little Sodium Amytal before reaching the critical sedation point; such a person should have a low sedation threshold. The introvert, on the other hand, whose cortex is in a state of considerable excitation and low inhibition, would require a considerable amount of Sodium Amytal before reaching the critical sedation point; He would be predicted to have a high sedation threshold. If he express this general hypothesis in terms of their standing on the extraversion-introversion continuum . . . then we would expect psychopaths to have the lowest threshold, followed by hysterics. Mixed neurotics would be intermediate, and anxiety states, obsessionals and reactive depressives would have high sedation thresholds.

FIG. 17.6. EFFECT OF SODIUM AMYTAL ON BIFRONTAL EEG

Note progressive increase of fast-frequency amplitude. Arrow points to inflexion point in the amplitude curve, which indicates sedation threshold.

(From Shagass, 1954)

Referring to Shagass's work Eysenck writes: "It will be seen that these results bear out our prediction in every detail" (Eysenck, 1957).

The age and weight of the individual are not a satisfactory basis for calculating the dose of barbiturate required owing to the great individual variation (Goodman and Gilman, 1955). The work of Shagass and of Eysenck suggests that certain psychological variables may well account for some of these variations.

EXPERIMENTAL PSYCHOLOGICAL STUDIES

The Persistence of Impairment as Measured by Psychological Tests

The effects of barbiturates have been less thoroughly studied by psychological methods than have the effects of the amphetamines. This is presumably because the demonstration of impairment of a function arouses less interest than attempts to demonstrate its improvement. Nevertheless, as barbiturates are so widely used, it is of practical importance to establish the extent of impairment of various functions in relation to the different barbiturates, their dosage and the time elapsing after their administration. In order to

do this adequately, especially if small doses are being used, careful experimental design and analysis are particularly necessary. This aspect will therefore be described in some detail.

Two careful experiments have been reported from the Anaesthesia Laboratory of the Harvard Medical School, using similar methods to assess the impairment of various functions following the oral administration of a hypnotic dose (100 mg) of pentobarbitone sodium (Goodnow *et al.*, 1951; von Felsinger *et al.*, 1953).

In the first experiments (Goodnow *et al.*, 1951) thirty normal young men were studied in two sessions, each lasting for two days and the intervening night. After an interval of five days the subjects returned for a second session and received the preparation (*placebo* or drug) which they had not been given previously.

Certain of the psychological tests administered failed to show a statistically reliable effect of the drug; these were tests involving: (1) arithmetic, (2) letter-crossing, (3) coding, (4) static steadiness, (5) visual choice reaction-time and (6) C.F.F. The tests which showed statistically reliable drug effects four hours after administration of the drug were (in order of sensitivity)—

1. Tapping speed (using a telegraph key).
2. Auditory reaction-time.
3. Time taken in naming opposites.
4. Memory for digits.

There was "highly suggestive" but not statistically significant evidence of impairment as long as fourteen hours after medication.

Von Felsinger *et al.* (1953) were able to demonstrate significant impairment in certain tests up to eight hours after ingestion of the drug (100 mg pentobarbitone sodium). Their experiment was similar in many respects to the one described above. Twenty subjects took part and were each tested twice in the two sessions. Eight tests were used, including—

- Visual perception,
- Serial learning,
- Recall,
- Associations to nonsense syllables,
- Attention,
- Computation, with and without distraction, and
- an
- Analogies test.

The tests of visual perception, attention and computation showed significant impairment after the drug. On the other hand, there was a significant increase in the number of associations to the nonsense syllables. Concerning this, the authors write that this "freer flow of internally determined ideas and associations . . . has, of course, been utilized in narcoanalytic

techniques." It is of interest that Welch *et al.* (1946) found a similar effect with dextroamphetamine sulphate, as these two drugs are in some respects antagonistic. Steinberg (1954) using a somewhat different association test, found that nitrous oxide produced a *decline* in verbal fluency, which she considered to be "of particular incidental interest . . . in view of the fact that nitrous oxide and similar drugs are often used in psychotherapy with the object of making the patient more loquacious."

Although Goodnow *et al.* (1951) did not find computation to be impaired by the drug, von Felsinger *et al.* (1953) found a statistically significant impairment, which they attributed to the fact that their subjects did not have the support to attention and concentration which is provided by pencil and paper. The effects of distraction during computation were less when the drug was given.

The tests of serial learning and analogies were unaffected by the drug, which is perhaps strange as the more complex functions are often supposed to be affected relatively more by drugs.

Von Felsinger *et al.* (1953) point out that their work provides "objective confirmation of the frequent complaint of 'hangover' after the use of pentobarbital sodium in ordinary hypnotic dose." Fastier (1955) concluded that 100 mg pentobarbitone sodium "was effective in inducing drowsiness and bringing about sleep more quickly than usual in less than half the subjects" who were investigated, but it was relatively more effective in causing hangover drowsiness (*see also* Lasagna, 1954). It is of interest that chloral hydrate (1.0G) was more effective in inducing sleep than 100 mg pentobarbitone sodium, as this drug (perhaps because it is not advertised as the barbiturates are) is "unfortunately neglected today" (Goodman and Gilman, 1955). Even half a century before Maurice Craig (*Psychological Medicine*, p. 449, 1905) complained that it was not used as much as it might be. Perhaps the time will come when the use of hypnotics will be based more than it is at present on careful comparative studies of their efficacy (e.g. Lasagna, 1954; Hare, 1955; Straus *et al.*, 1955; Pollack and Takakjian, 1955).

Effects on Cognitive Functions

The effects of amytal on intelligence were investigated by Slater, Sargent and Glen (1942) and Sargent *et al.* (1945), using the Cattell II Intelligence Test, which has two equivalent forms *A* and *B*. In the earlier experiments they obtained a statistically significant decrease in score on the test following the administration of gr 3 amytal. This decline, which was equivalent to 3-4 I.Q. points was confirmed by Sargent *et al.* (1945) who compared the effects of alcohol, amytal and caffeine, using the same test. In

all, three hundred and ninety-nine male psychiatric patients were tested, each receiving a *placebo* on the first day, half an hour before attempting form *A* of the test, and on the following day when form *B* was used receiving gr 3 of amytal, 20 c.c. of absolute alcohol diluted and disguised with essence of gentian or caffeine, or a *placebo*. Both alcohol and the barbiturate had a significantly deleterious effect. Although those who received alcohol only scored slightly less than those receiving amytal, their behaviour was noticeably different, the subjects often being euphoric, sleepy, inattentive and "full of backchat."

The Effects of Barbiturates on Learning

(i) *In animals.* There is some evidence which suggests that barbiturates impair conditioning (e.g. Wentinck, 1938) but conditioned reflexes may be established while the animal is under the influence of the drug to such an extent that the response is not elicited until recovery from the anaesthetic (Settlage, 1936; Headlee and Kellogg, 1941).

Dworkin *et al.* (1937) studied the effects of a variety of drugs on two dogs and two cats, which had been trained to lift the lid of a food container. Successive tests were made every two to six minutes. The animals were trained not to touch the lid during the interval ("interval inhibition") and to discriminate between two types of auditory stimuli. Five stages, corresponding to different doses of intravenous amytal, were recognized—

1. 5–7 mg per kg. Ataxia, but no effect on lid-lifting.
2. 15 mg per kg. Interval inhibition is replaced by lid-lifting.
3. 20 mg per kg. Negative stimuli now evoke responses, i.e. there is a breakdown of discrimination.
4. 25–30 mg per kg. The response to positive stimuli is delayed or lost.
5. 35 mg per kg. There is a loss of the unconditioned response, i.e. eating. Recovery occurs in 12–36 hours.

Both pentobarbitone sodium and alcohol had somewhat similar effects, their "outstanding effect" being the "decided weakening of the negative aspects of behaviour." This disinhibiting action probably accounts for the effects on mute and negativistic patients (described above), although they occur after relatively smaller doses (in terms of mg per kg).

The studies on the effects of barbiturates on learning have yielded rather discrepant results. Omwake (1933), Williams (1936), Williams and O'Brien (1937),

and Mendenhall (1940), all found that barbiturates had a detrimental effect on maze learning by rats: Coppock *et al.* (1956) found that one third of the anaesthetic dose of phenobarbitone tended either to preserve a previously established habit in rats (an avoidance response) or to interfere with the subsequent learning of an antagonistic response (i.e. in the opposite direction).

On the other hand, Fields (1935), Jones (1942) and Jones and Jones (1943) found that the drugged rats were not inferior in learning. Whereas Fields used a maze, Jones and Jones trained the rats on a discrimination problem, i.e. jumping on to one or other of two platforms having different patterns on them (an electric shock being administered if a choice was not made within ten seconds). If the wrong choice was made, the platform tipped, allowing the animal to fall into a net. The conclusion drawn from their experiments, which appear to have been well designed and carefully carried out, was "that large and prolonged doses of phenobarbital, within the limits of this experiment have no measurable effect on ability to learn a discrimination, and probably no effect on retention of what has been learned." The impaired learning which had previously been reported as a result of administration of the drug may be attributable to greater complexity of the task, ataxia (which would be a handicap in running a maze) or also to the diminution of the hunger and thirst drives, resulting from administration of the drug (Jones and Jones, 1943, but cf. O'Kelly and Weiss, 1955).

It has been claimed that repeated administration of a barbiturate can lead to a decrease in learning ability in rats which persists when the drug is no longer given (Marx and Edelstrom, 1950). Only the females were affected, and it is possible that their greater susceptibility to most barbiturates, which has been shown in several studies (Holck and Kanan, 1935; Holck *et al.*, 1937; Moir, 1937)¹ may have resulted in greater depression of eating during the four weeks when the drug was administered, and that their impaired performance was due to a dietary deficiency.

Another factor has recently been shown to be of importance by Dews (1955*a* and *b*, 1956). Using a Skinner box, he found that the effects of pentobarbitone sodium on pecking by pigeons were markedly influenced by the schedule of reinforcement, being greater on a fixed interval schedule than on the schedule according to which a reward was given for every fiftieth response. Blough (1956) has also demonstrated (in pigeons) the "insensitivity to drug effects

¹ Caution is necessary in generalizing from the rat to other animals. Holck and Kanan (1937) found no sex differences in barbiturate sensitivity in the dog, cat, rabbit, white mouse, turtle or frog; others have found women more resistant than men, resembling female guinea-pigs in this respect.

of behaviour maintained on a fixed-ratio schedule of reinforcement."

(ii) *In man*. The extent to which man resembles the rat in the characteristics of his learning is controversial, and too few studies have been carried out with barbiturates to ascertain how far the findings described above are applicable to man.

Three studies involving conditioning and learning have recently been carried out on the same group of subjects, approximately eighty female volunteers; they received at random one of four different treatments: (a) amytal gr 4½, (b) placebo, (c) Dexamphetamine sulphate, (d) the same drug as (c) but testing was begun after a longer interval (two hours instead of forty-five minutes). The tests which were given in the same sequence were (1) the acquisition of the conditioned eyeblink response (Franks and Trouton, 1958), (2) learning to operate a pursuit rotor (Eysenck *et al.*, 1957) and (3) the learning of nonsense syllables by the serial anticipation method (Willett, 1958). The experiments were carried out to test the predictions from Eysenck's theory concerning the differences between introverts and extraverts (Eysenck, 1955, 1957).

Amytal significantly impaired the number of conditioned eyeblinks acquired, but its effect on extinction was not significant (all comparisons being with the placebo group). (Details are given in Chapter 12, "Conditioning and Abnormal Behaviour," by Franks; cf. his Fig. 12.4 and discussion.) The curves obtained under the different conditions are similar to those obtained by Franks for dysthymics and hysterics (quoted by Eysenck, 1955; Franks, 1956) and therefore in accordance with Eysenck's theory (1957). Caution is necessary, however, in interpreting the results; the increase in activity with *d*-amphetamine has already been mentioned, and under the conditions of the experiment amytal tends to reduce the number of movements (Laverty and Franks, 1956); it also decreases action potentials from muscles (Jacobsen, 1944). In other words, the first drug tends to *decrease* and the second to *increase* the threshold for movements, and it may be this change in threshold rather than conditioning which is measured by the number of eyeblink responses (cf. Miller, 1956).

In the pursuit rotor experiment (Eysenck *et al.*, 1957), the amytal group had a significantly lower level of performance than the *d*-amphetamine group.

The study on serial anticipation learning of nonsense syllables carried out by Willett (1958) yielded few significant differences between the different conditions; the serial position effect, the number of associative errors and the number of trials to reach a criterion of one perfect repetition of the series did not differ significantly for any of the drug conditions. It is remarkable that a dose of amytal which was large enough to make many of the subjects appear as if

drunk (giggling and ataxia being commonly observed) had so negligible an effect on learning.

Perception

Trent (1947) found that gr 1½ of Nembutal (pentobarbitone sodium) enhanced contour clarity. The lowering of the threshold for flicker fusion has been confirmed in several studies (e.g. Landis and Zubin, 1951; Roback *et al.*, 1952); in barbiturate addicts, the drug has less effect and may even produce an effect in the opposite direction (Ideström, 1954). Neither amytal nor *d*-amphetamine significantly affect the rate of reversal of a Necker cube (Eysenck *et al.*, 1957).

Barbiturates have sometimes been used to facilitate obtaining responses to the Rorschach cards, particularly in those who are inaccessible, reluctant to respond or frightened, uncooperative (Kelley *et al.*, 1941) or suspected of incipient schizophrenia (Zuckerman *et al.*, 1954). Mûcher (1953) claimed that vague unrealistic stimulus material was perceived as more hostile, even ten hours after a barbiturate had been given.

Reaction-time

Goodnow *et al.* (1951) found a significant increase in auditory reaction-time four hours after the administration of 100 mg pentobarbitone; but Grünwald (1954) claimed that a dose of Evipan 10 per cent of the anaesthetic dose (as in Berg's 1949 study) resulted in a shorter reaction-time to visual and auditory stimuli; however, no measurements are given. Possibly the findings of Hill, Belleville and Wikler (1955, 1957) based on narcotic addicts, would be applicable to normal subjects, except that their attitude and reactions to morphine, which was used as a reward in both experiments, would be different. In the first study it was shown that pentobarbitone did not prevent the disruption of performance occasioned by electric shocks which resulted from slow visual motor reaction-times, whereas morphine prevented any significant effect on the reaction-times. In the second study (on one hundred and eighty-two former narcotic addicts), visual-motor reaction-times were measured after administration of (1) pentobarbitone, (2) morphine, and (3) no drug, under four incentive conditions (different morphine rewards). It was found that "in comparison with the control, both drugs acted either as 'stimulants' (accelerated reaction-time) or as 'depressants' (slowed reaction-time) or had no effect, depending on the particular incentives under which they were administered. The actions of these drugs, however, were 'specific' with respect to each other: the effect of pentobarbital changed from 'depressant' to 'stimulant' when conditions changed from 'Low Incentive' to 'High Incentive,' while the action of morphine changed from 'stimulant' to

'depressant' when identical changes in incentive level were made."

Slowing of reaction-time in barbiturate addicts following large doses of Seconal has been reported by Hill and Belleville (1953), and quickening of reaction-time following amyltal and amphetamine has been reported in depressives (Huston and Senf, 1952).¹

Psychological Experiments on the Effects of Barbiturates in Schizophrenia

Several studies have been carried out in an attempt to find quantitative evidence for the improvement which has been observed clinically in schizophrenics after the administration of amytal (e.g. Layman, 1940; Huston and Senf, 1952; Mainord, 1953; Ogilvie, 1954; Cohen, Senf and Huston, 1954; Huston, Cohen and Senf, 1955; Senf, Huston and Cohen, 1955; Cohen, Senf and Huston, 1956; Broadhurst, 1957). Both Layman (1940) and Mainord (1953) obtained statistically significant increases in intelligence test scores, although two more recent studies (Ogilvie, 1954 and Broadhurst, 1957) have failed to demonstrate any significant improvement. Improvement in some other tests has been observed but it appears to be less marked than the improvement in attitude (e.g. Huston and Senf, 1952).

The Effects of Barbiturates in Relation to Suggestibility and Hypnosis

The term "hypnosis" is used to describe the states produced by very different means, namely by drugs and by suggestion, and it is difficult to judge whether the similarities are merely superficial.

There appears to be agreement that barbiturates may facilitate hypnosis, but doubt concerning the resemblances between the states produced purely by one or other of these different means. Gorton (1949) maintains that the states induced by drugs "do not necessarily fulfil Hull's criteria of hypersuggestibility and it is not justifiable to place them under the heading of hypnosis. . . ." On the other hand, Wolberg (1948) points out that the drug "acts as a cortical depressant and produces the same phenomena as a hypnotically produced deadening of the cortical centers." Horsley (1943) states that several of the phenomena associated with hypnotic suggestion can be produced when the subject is merely under the influence of a barbiturate (e.g. postnarcotic amnesia, hyperamnesia and catalepsy may occur if suggested). However, the hypnotic phenomena are superimposed on the state of narcosis as a result of interaction

between the physician or experimenter and the patient, and not produced by the drug *per se* (Horsley, 1951). Furthermore an important difference is found in the EEG records; whereas the administration of a barbiturate intravenously produces certain characteristic changes in the EEG, these do not occur in hypnosis produced by suggestion and the EEG record resembles that of the normal waking state (Dynes, 1947 and Ravitz, 1951).

There is evidence that primary suggestibility and the capacity to be hypnotized are closely related (Eysenck, 1947). Numerous clinical observations testify to the increase in suggestibility which occurs with subanaesthetic amounts of anaesthetics (e.g. Starkey, 1917; Wilson, 1927) or barbiturates (Hauptmann, 1934; Stungo, 1941; Dicks, 1940; Rogerson, 1944). As different depressants appear to have similar effects on suggestibility, other drugs besides barbiturates will be included in the following account.

Baernstein (1929), using nineteen subjects, investigated the effect of subcutaneous injection of gr $\frac{1}{100}$ of scopolamine (hyoscine) hydrobromide on suggestibility, injection of saline being given as the placebo. The postural sway technique was employed. The subjects were tested one hour after the injection of the drug. Only eight subjects were responsive to suggestions following either the drug or the control dose. "It was found in general that subjects who were resistant to suggestion in the normal state were also resistant when under the influence of the drug. There was a fairly marked tendency, however, for those who were susceptible in the normal state to be markedly more susceptible when under the influence of scopolamine" (Hull, 1933). As Eysenck and Rees (1945) point out, Baernstein's experiment did "not include a vital control test, viz. a test of their ability to stand after the administration of the drug without any suggestion at all." Thus, all that may have been demonstrated was an increase in static ataxia.

To eliminate this factor, Eysenck and Rees (1945) used the Press-release test, for which the subject lies on a bed with his eyes closed, holding a rubber bulb, which is connected to a tambour whose movements are recorded by a kymograph. Heterosuggestion was provided by a gramophone record, and statements such as "you are squeezing the bulb . . ." were made for one minute. It had previously been shown that this test "measures essentially the same function as does the body-sway test. . . ."

Two groups of ten neurotic patients were selected on the basis of their body-sway scores, group A having proved to be uninfluenced by suggestion in this test, and group B highly influenced.

They were tested before and after the administration of the drug. Amytal was slowly injected intravenously, while the patient counted backwards from fifty;

¹ Numerous studies have been carried out, mostly on schizophrenics, using amytal and an amphetamine (e.g. Huston and Senf 1952-3, Cohen *et al.*, 1954, Cohen *et al.*, 1956, also Gottlieb *et al.*, 1952) but owing to limitations of space, the combined actions of these drugs cannot be described here.

when the counting became confused, the injection was stopped and the patient tested. The results, which were highly significant, indicated "that suggestible subjects are made more suggestible by Sodium Amytal injection, while non-suggestible subjects remain completely unaffected by the drug." (Italics omitted.)

That the results were due to the drug and not to a practice effect or suggestion was shown by injecting ten suggestible subjects with saline instead of amytal. In eight cases, there was no increase on retesting; in two cases, however, there was a marked increase.

An experiment similar to the one using the barbiturate was carried out using 45 per cent nitrous oxide in air (administered by means of a Minnitt-type apparatus), with similar results.

Eysenck and Rees give a theoretical interpretation of their findings based on Eysenck's (1947) theory of primary suggestibility.

Alcohol

Psychological experiments on the effects of alcohol have been carried out for well over half a century and the literature (much of which is in German) is vast. Fortunately, there is an excellent critical review of about forty thousand words in length and with nearly two hundred references covering the period up to 1940 by Jellinek and McFarland (1940). In the following, the account of the earlier work on alcohol is based largely on their review where further details and references may be found. As in their review, the scope here is limited to the acute psychological effects of alcohol and the chronic effects of alcohol are not discussed. Relatively little work appears to have been done on the former since 1940, most of the articles relevant to alcohol being concerned with chronic alcoholism and addiction (*see* reviews by Pullar and Strecker, 1948, 1949, 1951).

Jellinek and McFarland reanalysed the results of several of the earlier experiments and in some instances were able to show that the conclusions drawn by the original author were incorrect. As their review was approximately twice as long as this entire chapter which covers numerous other drugs it is obvious that much condensation is necessary. Only the main conclusions and the relevant references can be given here, supplemented by the seemingly scanty psychological work which has been done subsequently, some of which is reviewed by Goldberg (1943, 1949), Victor and Adams (1953). Jacobsen (1952) reviews the metabolism of alcohol. Although not yet available in this country, reference should be made to the *Classified Abstract Archives* of the literature dealing with alcohol, which was developed at Yale and is now sponsored by W.H.O. (Kellar and Efron, 1953).

As the pharmacology of alcohol is well known and

described in numerous books it need only be very briefly touched on here. Such subjects as the alcoholic

TABLE XVII.9
A SCALE OF TOXIC SYMPTOMS
(From Miles, 1932)

Per cent alcohol in blood	Subjective state and observable changes in behaviour under conditions of heavy social drinking
0.010	Clearing of the head. Freer breathing through nasal passages. Mild tingling of mucous membranes of the mouth and throat.
0.020	Slight fullness and throbbing at back of head. Touch of dizziness. Sense of warmth and general physical well-being. Small bodily aches and fatigues relieved. Not fretful about the weather nor worried concerning personal appearance. Quite willing to talk with associates. Feeling tone of pleasantness.
0.030	Mild euphoria, "everything is all right," "very glad I came," "we will always be friends," "sure I will loan you some money," "it isn't time to go home yet!" No sense of worry. Feelings of playing a very superior game. Time passes quickly.
0.040	Lots of energy for the things he wants to do. Talks much and rather loudly. Hands tremble slightly, reaching and other movements a bit clumsy; laughs loudly at minor jokes; unembarrassed by mishaps, "you don't think I'm drunk do you, why I haven't taken anything yet." Makes glib or flippant remarks. Memories appear rich and vivid.
0.050	Sitting on top of the world, "a free human being," normal inhibitions practically cut off, takes personal and social liberties of all sorts as impulse prompts. Is long-winded and enlarges on his past exploits. "Can lick anybody in the country," but has observable difficulty in lighting a match. Marked blunting of self-criticism.
0.070	Feeling of remoteness. Odd sensations on rubbing hands together, or on touching the face. Rapid strong pulse and breathing. Amused at his own clumsiness or rather at what he takes to be the perversity of things about him. Asks others to do things for him. Upsets chair on rising.
0.100	Stagers very perceptibly. Talks to himself. Has difficulty in finding and putting on his overcoat. Fumbled long with the keys in unlocking and starting his car. Feels drowsy, sings loudly, complains that others don't keep on their side of the road.
0.200	Needs help to walk or undress. Easily angered. Shouts, groans, and weeps by turns. Is nauseated and has poor control of urination. Cannot recall with whom he spent the evening.
0.300	In a stuporous condition, very heavy breathing, sleeping and vomiting by turns. No comprehension of language. Strikes wildly at the person who tries to aid him.
0.400	Deep anaesthesia, may be fatal.

content in different drinks and the differential rates of absorption from these, the influence of food on the rate of absorption, and calculation of the blood-alcohol level, and the diagnosis of intoxication have all been intensively investigated, but the findings must be omitted here owing to lack of space.

Table XVII.9 which is taken from Miles (1932) shows the relation between the percentage of alcohol in the blood and the overt behaviour. In this connexion, it should be remembered that the effects of alcohol are very variable (Meerloo, 1947) and may even vary in the same person according to the different circumstances in which the alcohol is taken. The degree of disturbance of behaviour is affected also by the rate and direction of change of the alcohol in the blood-stream, being greater if the concentration is increasing; this is of importance because it means that a single test given a particular interval after the ingestion of alcohol may give a misleading impression of the susceptibility of the subject to alcohol, as was pointed out by Eggleton (1941) who advocated repetition of the test every ten minutes until recovery had occurred.

There are certain methodological disadvantages which are encountered in many studies of alcohol. One is that a *placebo* has rarely been used; this is partly because many of the experiments were conducted before the need for *placebo* was generally recognized, and partly because it has been widely believed that owing to the distinctive flavour of alcohol it is impossible to disguise it or to make a convincingly tasting *placebo*. Nevertheless, there are exceptions; for instance Hollingworth (1923, 1924) used de-alcoholized beer which the subjects were unable to distinguish from the ordinary beer on the basis of its taste.

PSYCHOLOGICAL EXPERIMENTS

As far as possible the main findings concerning the effects of alcohol have been condensed in tables. The references given in square brackets are taken from a review by Jellinek and McFarland (1940) whose conclusions, as was pointed out, do not always coincide with the original author. It has been necessary here to omit certain factors, which should not, however, be ignored in the studies on alcohol. Among the factors are—

1. The absolute amount of alcohol received. Probably the most commonly used dosage has been 35 c.c. of absolute alcohol given in a 20 per cent solution. If it is assumed that for every 0.01 per cent of alcohol in the blood, from 5–10 c.c. of alcohol must be ingested (Goodman and Gilman, 1941) this corresponds to a blood-alcohol concentration of about 0.04 to 0.07 per cent (i.e. 40–70 mg

of alcohol per 100 ml of blood). This results in subclinical intoxication in the majority of adults.¹

2. (a) Its dilution, and (b) the type of beverage, e.g. whether it is diluted, absolute alcohol or beverage wine, etc. (Haggard *et al.*, 1938; Newman and Abramson, 1942).

3. The total volume of liquid consumed.

4. The speed of drinking.

5. The time after the last meal, and also the nature of the meal (e.g. fats tend to delay absorption).

6. The drinking habits of the experimental subjects, e.g. moderate, habitual, abstinent, etc.

7. The time elapsing before testing, and whether the concentration is rising or falling.

Other details, such as the experimental design, cannot be conveniently tabulated and, unless these are known, merely stating the number of subjects tested is apt to be misleading. In a remarkable number of experiments with alcohol there has been only one experimental subject and that has very often been the experimenter himself; thus a certain amount of caution is required both in the interpretation and in the attempts to generalize the results.

The main findings on the psychological effects of alcohol are summarized in Table XVII.10 (cognitive functions), Table XVII.11 (associative functions), Table XVII.12 (sensory and perceptual functions) and Table XVII.13 (a) and (b) (motor functions).

The distinction between the unskilled and the skilled motor tasks is not a fundamental one but mainly a matter of degree; even in the ergograph studies, skill and practice effects are marked and a variable amount of co-ordination is required as well as a muscular strength. It will be noticed in Table XVII.13 that small amounts of alcohol have been found to improve performance on the ergograph, at least for a short period. This is one of the very few instances where alcohol has been found to have a beneficial effect. The explanation of it given by Starling is: "In exceptional circumstances a moderate dose of alcohol may for a time abolish the sensation of fatigue, or create an emotional drive which will enable an individual to overcome temporarily the effects of fatigue, so making capable of continuing his efforts beyond the period at which they would otherwise have to come to an end. This increased work is in the nature of a call upon capital, which must be repaid later by a prolongation of the period of rest." It has sometimes been said that alcohol may have first a stimulating and then a depressing effect on the performance on the ergograph. This apparent depressant effect is due to the decrease in efficiency which occurs in any case, but

¹ For details of "The Recognition of Intoxication," see the *B.M.A. Special Committee Report*, 1954.

TABLE XVII.10
THE PSYCHOLOGICAL EFFECTS OF DRUGS: ALCOHOL
COGNITIVE FUNCTIONS

Function	Test	Type and number of subjects	Author and date	Effect	Comment
Intelligence		50 normal subjects	Cattell (1930)		Conclusions invalid because they depended upon the comparison of mean deviation scores. (See Jellinek and McFarland (1940), p. 360.)
	Naming of opposites	6 normal subjects	Hollingsworth (1923-4)	Impaired	
	Colour naming	6 normal subjects	Hollingsworth (1923-4)	Increase in errors	Impairment in proportion to the dose.
	Colour naming	14 normal subjects	McFarland and Barach (1936)	Increase in errors	
Reasoning	Cancellation of letters	25 boys	[e.g. Erlacher and others quoted by Jellinek and McFarland Table 16, 1940] ¹	Impaired	The effect on the 10-year-old boys was twice as great as on the 14-year-old boys.
	Arithmetical reasoning	20 normal subjects	[Joss (1900)]	Impaired	
	Judgement of sorites, syllogisms and conversions	12 normal subjects	Seward and Seward (1936)		Although it was claimed that 0.75 G per kg body weight of alcohol had no effect, Jellinek and McFarland (1940, p. 360) point out that there was a marked practice effect which was lowered considerably by the alcohol.
	Artificial language test	6 normal subjects	Mead (1939)	Loss of efficiency	"An excellently devised experiment" (Jellinek and McFarland, 1940, p. 359).
Judgement of time	Driving	20 normal subjects	Vernon (1936)	Impaired	Some subjects considered that they were in fact driving more quickly.

¹ When the names of authors in Tables XVII.10, XVII.11, XVII.12 and XVII.13 are enclosed in square brackets, this indicates that the original sources have not been consulted, but the findings taken from Jellinek and McFarland (1940), where the references are also to be found

which appears to be less marked after a moderate dose of alcohol. Larger doses of alcohol either do not influence the work output or lower it (see Jellinek and McFarland, 1940).

In Table XVII.13 (b) no attempt has been made to assess the psychological functions involved in the tasks, which are all highly complex.

Simple Reaction-time

Simple reaction-time has been extensively investigated (see Jellinek and McFarland). It was originally claimed by several workers, including Kraepelin, that the initial effect of alcohol on reaction-time was to shorten it. After careful reanalysis of the work upon which this conclusion was based Jellinek and McFarland concluded—

1. That tests of reaction-time involved a strong practice trend.

2. That the effects of small doses of alcohol (10 c.c.) do not overcome this practice effect in the first twenty minutes following its illustration.

3. That the effect of larger doses is to increase the reaction-time immediately.

"The oft-reported initial shortening appears to be an arithmetical artefact inherent in averages based on the entire pre-alcohol period." Jellinek and McFarland emphasize that the applicability of the laboratory tests on reaction-time to actual road conditions in driving a motor-car is "not beyond question." Hicks (1956) has also stressed that reaction-time "looks like a physiological reflex but is actually an acquired skill . . ." which is considerably influenced by the attitude of the subject (sensory or motor) and also by the "nice assessment of the proportion of errors (false reactions) one can get away with."

TABLE XVII.11
THE PSYCHOLOGICAL EFFECTS OF DRUGS: ALCOHOL
ASSOCIATIVE FUNCTIONS

Function	Test	Type and number of subjects	Author and date	Effect	Comment
Memory	Continuous addition	7 normal subjects	[Kraepelin, 1892]	Impairment	Since confirmed in numerous other studies (see Jellinek and McFarland (1940), Table 32).
		11 psychotics	[Göring, 1911]	Great variation, 3 improving and the rest showing impairment	
		4 groups of about a dozen girls and boys each of two age groups, 10 and 14	[Erlacher, 1926, 1931]	Impairment, especially of performance by the 10-year-old girls which was twice that of the boys of that age	Alcohol was administered on 5 of the days.
	Free association to a standard list of words	One subject (Kraepelin) tested on 17 consecutive days	[Kraepelin, 1892]	Fewer new associations apart from clang associations	
	Continuous free association	1	[Kraepelin, 1892]	Incidence of superficial associations increased	
	Controlled association (supraordinates)	1	[Kraepelin, 1892]	Tendency to disregard rules and respond with synonyms, etc.	
	Continuous free association tests	6 normal subjects	[Kurka, 1928]	Kraepelin's findings largely confirmed	
			c.g. Hollingworth (1923), McFarland and Barach (1936)		"There is no doubt that immediate memory is adversely affected by alcohol. . . ." (Jellinek and McFarland (1940), p. 353). Most tests have also measured learning.

TABLE XVII.12
THE PSYCHOLOGICAL EFFECTS OF DRUGS: ALCOHOL
SENSORY AND PERCEPTUAL FUNCTIONS

Function	Test	Author and date	Effect	Comment
Tactile	2-point discrimination	[Lichtenfels, 1851; Kremer, 1884]	Increase in threshold	See Jellinek and McFarland, 1940, pp. 312-317
Pain	Absolute threshold	[Mullin and Luckhardt, 1934]	No effect	
	Pain threshold		Increased	
Visual	Faradic threshold	[Dodge and Benedict, 1915; Miles, 1932]	Inconclusive	
	Sensitivity to light	[Lange and Specht, 1914]	Increased	
	Threshold of discrimination of light intensities	[Lange and Specht, 1914]		
Auditory	Visual acuity	[Busch, 1912]	Improvement claimed but reanalysis by Jellinek and McFarland (1940) showed that impairment occurred	
	Threshold of discrimination	Miles (1924)	Impairment	
	Auditory sensitivity	[Specht, 1910; Hansen]	Impairment Inconclusive	

TABLE XVII.13
THE PSYCHOLOGICAL EFFECTS OF DRUGS: ALCOHOL
MOTOR FUNCTIONS

Function	Test	Type and number of subjects	Author and date	Effect	Comment
(a) <i>Unskilled</i> Muscular strength	Ergograph	(see text for further details)		"Small dosages (10–20 c.c.) of alcohol have been generally found to increase the muscular output above the initial level for at least a short while. In medium dosages (30–45 c.c.) the increase is less pronounced, and large dosages (60–80 c.c.) result either in no change or in deterioration of the performance" (Jellinek and McFarland, 1940)	
Co-ordination	Velocity of eye movements	6 subjects	Dodge and Benedict (1915)	Impairment in terms of time	Co-ordination is also involved in ergograph work
	Finger movements	6 subjects	Dodge and Benedict (1915)		
	Tracing pathways	8 subjects 25 subjects	Miles (1924) [Bahnsen and Vedel-Petersen (1934)]	Impairment in terms of errors	
	Pursuit meter	8 subjects 14 subjects	Miles (1924) McFarland and Barach (1937)	Impairment	
(b) <i>Skilled</i>	Typewriting	7 subjects (not professional typists)	Vernon <i>et al.</i> (1919)	Great increase in errors	As numerous functions are involved, only the tests are listed here. Subjects were moderate drinkers Subjects were <i>habitual</i> drinkers Two other experiments on 1 and 2 subjects respectively are in accordance with this (Jellinek and McFarland, 1940)
	Typesetting	5 professional typists 4 skilled typesetters	Miles (1924) [Aschaffenburg, 1896] [Erlacher, 1926, 1931]	Moderate increase in errors but slight effect on speed Increase in speed but no increase in errors Impaired

	Threading needles	Controlled self experiments on 43 consecutive days	Tottermann (1916), quoted by Miles (1932)	Impaired performance	

THE EFFECTS OF ALCOHOL ON DRIVING

The role of alcohol in motor accidents is well known. Reference is made to the earlier work by Heise and Halporn (1932), Heise (1934), Vernon (1936), Cavett (1938) and others in the reviews by Jellinek and McFarland (1940) and Drew (1950).

A carefully conducted experiment on thirty-seven skilled drivers, who were mostly accustomed to drinking moderate amounts of alcohol, was carried out by Bjerver and Goldberg (1950) who also give references to much of the recent literature. They found the threshold of impairment of the driving ability of their subjects to be 0.35 to 0.40 per mille (0.035 to 0.04 per cent) in the blood. Drew (unpublished) investigated the effects of alcohol on a simulated driving problem, and found that there was a small increase in error score when the blood-alcohol level was in the range 30–50 mg per 100 ml; the speed of driving increased with small doses and fell off with larger doses, the peak speed occurring after the ingestion of about 0.35 g per kg body weight. "Statistical analysis showed that the blood-alcohol level was best for predicting . . . what the performance would be ten minutes *after* sampling; whereas the urine-alcohol level was best for estimating what the performance had been ten minutes *before* sampling.

ALCOHOL AND PERSONALITY

Although alcohol has such marked effects on the personality, these have been largely ignored, and there are remarkably few studies which are directly relevant. Hollingworth, on the basis of his studies of the effects of alcohol and caffeine on small groups of subjects, states: "There is a very striking negative correlation between final proficiency and susceptibility to the effects of alcohol . . ." and he concludes: "Drug resistance is positively correlated with general competence." (Hollingworth, 1923–4, *see also* Hollingworth, 1925 and 1931). This suggests that the neurotic may be more susceptible, and Newman (1935) found that they tended to respond differently from normal subjects following the intravenous injection of alcohol, e.g. in his series of fifty, depression and crying occurred in 34 per cent of neurotics and 45 per cent of schizophrenics but in none of the normal subjects. (The schizophrenics were differentiated from both the normal and most of the neurotic subjects by their loss of contact with reality following the injection.) According to McDougall's (1929) theory, which has been recently extended by Eysenck (1957), the extravert would be expected to be more susceptible to the effects of alcohol than the introvert, and the effects of alcohol are also claimed to be extraverting. There is as yet no direct experimental evidence for the theory based on experiments with alcohol.

There have been numerous studies of the personality

traits of alcoholics; thirty-seven of these are summarized by Sutherland *et al.* (1950) who conclude: "No satisfactory evidence has been discovered that justifies a conclusion that persons of one type are more likely to become alcoholics than persons of another type. This conclusion agrees with the clinical findings of Wexberg (1949) that 'There is no alcoholic personality prior to alcoholism'." However, Parnell (1955) has found some evidence for a correlation between body build and alcohol consumption, which is greater in endomorphs than those with other physiques.

Just as the reasons for drinking are various, considerable heterogeneity is found among alcoholics, which has recently been demonstrated using factor-analytical methods (Schaefer, 1954; Markkanen, 1957).

Horton (1943) studied data from fifty-six primitive societies and found evidence in favour of the relationship between anxiety and the consumption of alcohol; this is in accordance with the findings cited in the section on the effects of alcohol in animals, and compatible with Dollard and Miller's (1950) theory. However, numerous other factors are doubtless involved, such as a low alcohol limen (Martensen-Larsen, 1950), and there is some evidence that alcoholism may be a "genetotrophic" disease, i.e. "one arising fundamentally from nutritional deficiency which in turn has its basis in a genetically controlled augmented requirement for one or more specific nutritional elements" (Williams *et al.*, 1949).

EXPERIMENTS ON THE EFFECTS OF ALCOHOL IN ANIMALS

There are numerous reports of impairment in animals as a result of alcohol (complex maze habits are disturbed more than simple ones (Varner, 1933)), and Miller and Miles (1936) found (a) that alcohol caused a decrease in speed and an increase in variability, and in the number of errors; (b) that a succession of non-rewarded trials led to similar effects and that the combination of (a) and (b) had an effect in the maze situation very much greater than the sum of the separate effects.

The effects of alcohol on conditioning are discussed in another chapter by Franks, and on "experimental neuroses" by Broadhurst. The effect on conditioning is similar to that described for barbiturates (e.g. Andreyer, 1934; Dworkin *et al.*, 1937). The conclusions from the animal experiments of Masserman (1944), Masserman and Yum (1946), Bailey and Miller (1952) and Conger (1951) may be of some relevance to the motivation of humans in taking alcohol. Masserman showed that whereas the administration of alcohol to normal cats resulted in a loss of the most complex and recently learned adaptive patterns, in some "neurotic" cats it resulted in the re-establishment of more nearly normal responses, but most of

the cats developed a preference or "addiction" to alcohol until their "neuroses" were relieved by other means. Conger (1951) found that alcohol decreased the strength of avoidance motivated by fear in normal rats, and this was confirmed for cats by Bailey and Miller (1952). Dollard and Miller (1950) hypothesized that alcohol (and the barbiturates) "produce a greater reduction in the strength of fear than they do in that of other drives. Thus they lower the gradient of avoidance more than that of approach." This reduction in strength of fear and conflict reinforces the "responses" involved in drinking, which thereby become learned. These findings accord well with Eysenck's theory.

Narcotics and Analgesics

Owing to limitations of space and also the fact that morphine and similar compounds are rarely used in psychological experiments in man (except "post-addicts"), the relief of pain by drugs and the other effects caused by these drugs can only be briefly mentioned. Details of the action of morphine and related drugs on the central nervous system are given in the comprehensive and excellent review by Wikler (1950).

A new impetus was given to the experimental measurement of pain threshold and of the effects of drugs upon it, by Hardy, Wolff and Goodell (1940) who developed a thermal radiation method which has been extensively used. Hardy (1956) reports that the pain threshold obtained by this method does not differ appreciably in subjects of different sex, age, race and cultural background, but several other investigators have failed to confirm this uniformity (Beecher, 1956*a* and *b*), and the significance of the effects of narcotics and analgesics on pain threshold remains matter of controversy. Wolff, Hardy and Goodell (1940, 1941) found that morphine, aspirin and other analgesics raised the pain threshold, but Harris and Blockus (1952), using tooth pulp algesimetry, found that aspirin (0.65 G), in contrast to codeine, did not raise the threshold any more than did a *placebo*; on account of this, they even questioned whether aspirin was an analgesic. On the other hand "the existence of any dependable relationship between the effects of analgesic agents and the pain threshold" has been doubted by various workers including Beecher (1956) and his colleagues (e.g. Keats *et al.*, 1950), who have emphasized the importance of the reaction to pain rather than the pain threshold, and have argued that the potency of analgesics should be assessed in a clinical situation by measuring their effects on naturally occurring pain (Keats, Beecher and Mosteller, 1950).

That an important part of the effect of an analgesic is attributable to the influence on the reaction to pain and the diminution of anxiety has received support

from the experiments of Hill, Kornetsky, Flanary and Wikler (1952), Hill, Belleville and Wikler (1954), Kornetsky (1954) and Hill (1956). (For a recent discussion of the effects of analgesics and the nature of pain, see the Symposium on this subject, *J. Chronic Dis.* 4, 1-110, 1956).

ASPIRIN (AND CORTISONE)

The psychological effects of ordinary doses of aspirin on nonsense syllable learning (Jones, 1933) and on various functions such as addition, coding, opposites test, steadiness and reaction-time (Davis, 1936) are negligible. It is of interest that a psychosis has been reported attributable to large doses of aspirin (Bowman, 1933), in view of the finding that cortisone (which may also produce a psychosis), has turned out to be like aspirin in its effects on rheumatoid arthritis, although perhaps not as satisfactory (*M.R.C. Report*, 1957). Incidentally, although there are clinical reports of the psychological effects of cortisone and ACTH (e.g. Rees, 1953; Lewis and Fleminger, 1954; Fleminger, 1955; Drake, 1954; Fox, 1955) no easily detectable changes in test performance appear to occur with cortisone (Chance and Lotsof, 1955).

Tobacco

Although Rivers (1908) observed no appreciable effect, increases (Berry, 1917) and decreases (Bush, 1914) in efficiency have been attributed to smoking, about which there has been much controversy (e.g. Earp, 1927; Hopkins, 1938). The psychological effects in smokers and non-smokers were carefully investigated by Hull (1924) who found that only three of the twelve forms of behaviour studied were definitely affected, two of which were physiological (pulse and tremor), the other being addition, which was impaired in non-smokers and improved in habitual smokers. Fay (1936) found that the smoking *situation* had little effect on simple and choice reaction-times. However, such studies appear rather trivial in comparison with the probable long-term carcinogenetic effects. (It is of interest that whereas the correlation between smoking and carcinoma of the bronchus is supposed by the tobacco manufacturers not to indicate a causal relationship, a non-causal interpretation has not apparently been suggested for the correlation between alcohol and its apparent effects.)

Anoxia

Low oxygen tension may impair performance on a variety of tasks in a manner similar to that of depressant drugs, more complex functions being impaired sooner than simpler ones (McFarland, 1932, 1939). Neurotics appear to be more susceptible than normal subjects (McFarland and Barach, 1937; Hertzman *et*

al., 1944). Impairment after alcohol is reduced by giving oxygen (McFarland and Barach, 1936) and there is some evidence that amphetamine helps to counteract the effects of oxygen lack (Seitz and Barmack, 1940) and similarly that raising the blood-glucose level tends to reduce the effects of anoxia (Richter, 1949-50). A detailed consideration of the effects of anoxia on perception will be found in Chapter 3 by G. Granger on "Abnormalities of Sensory Perception."

Nitrous Oxide

The administration of this gas, usually in the proportion of 30 per cent nitrous oxide to 70 per cent of oxygen, breathed in through a face mask, has a depressant effect on the central nervous system, and has been found by McKinney (1932) and Steinberg (1954) to affect immediate memory adversely; similarly Russell and Steinberg (1955) have found slower learning of a temporal maze. Results such as these are capable of two interpretations; the effect of the drug may be primarily on the *formation* of associations, or on their *availability*. In the studies mentioned both learning and test performance were carried out under the influence of the drug, thus confounding these two effects.

Nitrous oxide lends itself particularly well to studies in which an attempt is made to separate out these two effects because the drug is rapidly excreted, and subjects return to a normal state almost immediately after withdrawal of the drug. Two experiments of particular interest from the methodological point of view have been reported in this connexion by Steinberg and Summerfield (1957). In the first of these, nonsense syllables were learned by two groups equated for learning ability. The control group breathed air during the learning period, the experimental group breathed 30 per cent nitrous oxide. An interval of 12.5 min was introduced between the fifteenth and sixteenth trials, during which and subsequent to which the drug group reverted to breathing air. The failure of the drug group to improve their score during the interval suggests strongly that the effect of the drug is on *acquisition* rather than *performance*; that is:

"It acts so as to impede the formative processes, and does not merely obscure the progress of learning by blocking responses."

In the second experiment, Steinberg and Summerfield employed three groups. Group C, the control group, breathed air throughout. Group E_1 breathed air during the initial learning and nitrous oxide during the interval. Group E_2 breathed nitrous oxide throughout. The hypothesis tested in this experiment,

FIG. 17.7. LEARNING CURVES FOR THE AIR/AIR, AIR/DRUG AND DRUG/DRUG GROUPS (TEN SUBJECTS IN EACH GROUP) PLOTTED IN TERMS OF MEAN NUMBER OF SYLLABLES CORRECTLY ANTICIPATED PER TRIAL
(From Steinberg and Summerfield, 1957)

which was identical in its general arrangement with the previous one, was as follows. According to the interference theorists, forgetting results because extraneous associations disturb the pattern built up during learning. If nitrous oxide is administered *immediately after learning*, this should reduce forgetting because, by impairing the formation of new associations, it should reduce interference. The results of the experiment are shown in Fig. 17.7. It will be seen that Group C, which breathed air during the interval, showed a *deterioration* of performance, while there was no such deterioration in Groups E_1 and E_2 . The results therefore strongly support the general hypothesis. Quite generally these results are deducible from Eysenck's general theory (1955).

AUTONOMIC DRUGS

This section is concerned chiefly with the drugs which mimic or block the action of the peripheral autonomic nervous system, sympathetic or parasympathetic. There are thus four groups—

1. Sympathomimetic (adrenergic).
2. Sympatholytic (i.e. blocking).

3. Parasympathomimetic (cholinergic).
4. Parasympatholytic (i.e. blocking).

Several drugs already discussed have some of the properties of the drugs in these groups, for example amphetamine is sympathomimetic. Adrenaline and nor-adrenaline are the main examples of group

(1), acetylcholine and Mecholyl of group (3) and atropine of group (4). Groups (1) and (4) have some properties in common, such as dilatation of the pupil, and likewise groups (2) and (3). Hexamethonium and tetraethylammonium compounds, which have also been used in psychological experiments, are both parasympatholytic and sympatholytic.

Preganglionic nerves and nerves to voluntary muscles are cholinergic (nicotinic) whereas the postganglionic parasympathetic fibres and the sympathetic fibres to sweat glands are cholinergic (muscarinic). The postganglionic sympathetic fibres are adrenergic. Atropine antagonizes the muscarinic action peripherally, and cocaine and ephedrine potentiate the peripheral adrenergic actions.

This very brief and arid account must be borne in mind for the actions of drugs acting on the autonomic system to be intelligible. It should be emphasized, however, that the central effects of these drugs are probably of even greater importance psychologically, and much remains to be discovered about the role in the central nervous system of the peripheral synaptic transmitters, and of substances such as 5-hydroxytryptamine. Another drug to be included in this section is histamine, although it is not strictly speaking an autonomic drug; it is a substance produced peripherally by tissue damage, but its role in the central nervous system is not yet decided.

Adrenaline and Nor-adrenaline¹

The ability of adrenaline to produce effects characteristic of stimulation of the sympathetic system has long been recognized (Langley, 1901; Elliott, 1905) and the role of this system in the emergency reactions of "fight or flight" is familiar from the work of Cannon (e.g. 1915, 1929, descriptions of which will be found in most textbooks of physiology or psychology). Recently, adrenaline and its derivatives have assumed a new importance owing to their possible role in certain psychoses.

CLINICAL DESCRIPTIONS

There has been a somewhat sterile controversy as to whether the injection of adrenaline can give rise to a "true" emotion. The difficulties are in part empirical (the solutions of adrenaline often being impure and there being large individual variations), and in part semantic. Part of the controversy arises from the ambiguity of the concept of "emotion" which, as Duffy (1951) has pointed out, is an example of a dual concept, incorporating "two aspects of behaviour which may vary independently," namely *energy mobilization* and the *direction* of behaviour. "It so happens that the administration of adrenaline affects

the energy level of behaviour but not its direction," there usually being no environmental situation towards which this additional energy could be meaningfully directed.

Maranon (1924) found that adrenaline injection sometimes resulted in an affective state in which the subjects described themselves as feeling *as if* afraid, or *as if* their emotions were aroused, etc., but in only a few instances was there evidence of genuine emotion. Cantril and Hunt (1932) concluded that "in general the injection of adrenaline is not sufficient to produce an emotion," as the intellectual content (i.e. the object or situation towards which the emotion is directed) is usually not present. Richter (1940) considered that adrenaline normally does not give rise to "true emotion but emotion with insight," and when the former does occur it is because "the subject becomes conscious of the coenaesthetic impulses arising as a result of the somatic disturbance and begins to think of emotional experiences in which he has felt a similar sensation. . . ." In current jargon, this is an example of positive feed-back. Darrow and Gellhorn (1939) demonstrated that "the secretion of adrenaline into the circulation is itself an effective damping mechanism for reducing the reactions induced by sympathetic excitation"; this might be regarded as equivalent to negative feed-back, which has also been demonstrated by Callaway and Thompson (1953). Callaway (1955) quotes evidence that procedures which evoke sympathetic activity (and stimulation of the ascending reticular system) may "create a limited sensory environment." In this way he has attempted to link up the production of hallucinations by sympathetic substances with their production by restriction of sensory stimulation.

Although Landis and Hunt (1932) maintained that the various mental disorders showed no differences in susceptibility to adrenaline, Lindemann (1935) who investigated the effect of intramuscular injection of 1 ml of 1:1,000 solution of adrenaline on forty-eight patients found that apathetic schizophrenics showed little response (cf. Freeman and Carmichael, 1935), whereas acute schizophrenics and "active psychoneurotics" showed the most marked changes. Sometimes, however, the same patient reacted differently when retested. Lindemann also noted that there was characteristically a reduction in speech and motor activity, accompanied by increased self-concern and decreased interest in the outside world. Kraines and Sherman (1940) were unable to find a significant difference in the cardiovascular effects of adrenaline between neurotic and normal groups.

Subsequently Lindemann and Finesinger (1938, 1940) studied the effects of injection of (1) saline, (2) adrenaline, (3) Mecholyl (acetyl-methylcholine chloride), a cholinergic compound. In the first study,

¹ "Epinephrine" and "nor-epinephrine" are synonyms for adrenaline and nor-adrenaline respectively.

they tested twenty patients who were prone to distinct attacks of anxiety but had relatively free intervals, and found that these could be divided almost evenly into four groups, those in whom—

- (a) adrenaline reactivates a typical attack,
- (b) Mecholyl reactivates a typical attack,
- (c) both drugs reactivate a typical attack,
- (d) neither drug has any effect on the anxiety state.

A marked adrenaline response was found in patients who had overwhelming attacks of distress, coming on without provocation and not related to specific situations or to a specific content. Their distress might be labelled depression, anxiety or worry . . . The markedly positive response to Mecholyl was exhibited, on the contrary, by persons who had developed definite phobias and concrete fears. Their reaction was one of panic, with alert eagerness to cope with a threatening situation, in contrast to the adrenaline group, where the patient was overwhelmed by an indefinable wave of distress concerning which he does not attempt any intellectual elaboration.

Those in group (c) had a history of instability of the autonomic nervous system, and in group (d) were patients with more serious personality difficulties.

The symptoms produced by these injections were more fully described in a later article by Lindemann and Finesinger (1940). Twenty-four (out of forty) patients referred to feeling happy after Mecholyl, whereas this was never reported after adrenaline which tended to cause worry, depression and anger (cf. Jerrild and Thomas, 1931). Myerson *et al.* (1937) found no evidence of a change in the mental reactions of eighteen schizophrenics who received injections of Mecholyl, but Funkenstein *et al.* (1948) found that adrenaline or Mecholyl sometimes precipitated anxiety in schizophrenics, although not as often as in anxiety neurotics (cf. Dynes and Tod, 1940).

Lindemann and Finesinger's observations on the effects of these drugs on mood and behaviour suggest that the injection of adrenaline may make patients more dysthymic, i.e. more introverted and more neurotic. "Under the influence of adrenaline the patient appears self-absorbed, hesitant, inhibited and quite preoccupied with his symptoms," whereas with Mecholyl "the whole picture is that of vivaciousness, eagerness. There is occasional euphoria, relaxation and relief" (Lindemann and Finesinger, 1938). Similarly, under the influence of adrenaline the patient speaks little, whereas with Mecholyl the effects are just the opposite.

PSYCHOLOGICAL EXPERIMENTS

Psychological experiments on the effects of adrenaline are regrettably sparse. Jerrild and Thomas (1931) investigated the effects on performance tests by

six subjects and claimed that adrenaline "did not favour mental efficiency, while the motor activities [strength of grip and tapping] were somewhat improved . . . in spite of the tremor which it caused." Landis (1935) was unable to demonstrate that it had any effect on dart throwing.

Since then a report has appeared of experiments "to explore whether prolonged intravenous adrenaline infusion at a low dose level reactivated habitual idiosyncratic anxiety patterns in normal persons." Also included were the effects "on certain cardiac indices and on psychological and motor performance known to be disturbed in anxiety" (Basowitz, Korchin and Oken, 1955; Basowitz *et al.*, 1956).

There were twelve subjects, aged 24–28, and each was investigated on three occasions, the first being devoted to a clinical interview, and on the subsequent two visits each subject received an adrenaline or saline infusion. The following tests were administered while the infusion was in progress: (1) flicker fusion frequency, (2) hand steadiness, (3) memory for digits, (4) physical persistence, (5) the Stroop task [stressful colour-naming], (6) motor inhibition and (7) word fluency under distraction. The subjective changes and the cardiovascular effects were also studied.

Only "the more clearly motor tasks" were affected among all these tests. "Hand steadiness, physical persistence and motor inhibition showed a statistically significant decrease with adrenaline, steadiness at the 0.001 and the others at the 0.05 level of confidence. No noteworthy trends were apparent on the remaining procedures of the battery" (Basowitz *et al.*, 1955).

In almost all subjects pulse pressure and rate were increased, and the commonest subjective response was an awareness of this. Mild apprehensiveness under adrenaline was described by seven individuals. "There was a distinct tendency for adrenalin to elicit personally-patterned symptoms consistent with the individual's past history of anxiety." In one subject with a long history of labile anxiety, they were able to turn on and off a full-blown free anxiety reaction by alternately switching in and cutting out the adrenaline infusion. "On the other hand, constricted personalities who tend to encapsulate affect failed to show appreciable subjective changes." There was a total of sixty-six symptoms in all the adrenaline sessions combined (compared with twenty-one in the saline, this figure being in part attributable to apprehensiveness occasioned by the unfamiliar surgical procedure).

Some of the effects of adrenaline infusion on psychological performance have been observed in neurotics or in normal subjects under stress (see Lazarus, Deese and Osler, 1952, for a summary of the latter). Hand steadiness and physical persistence tend to be decreased in neurotics (Eysenck, 1947) and the fact that these are also decreased by the adrenaline infusion

suggests that this causes an increase in neuroticism. However, the digit span test was not affected, yet there is evidence that this is a measure of anxiety (Moldawsky and Moldawsky, 1952). In addition, there was an effect on motor inhibition, which was decreased. According to Eysenck (1947) lessened motor control is characteristic of extraversion (or hysteria).

THE DIFFERENTIAL EFFECTS OF ADRENALINE AND NOR-ADRENALINE

Some of the effects of what was thought to be adrenaline were puzzling until it was recently realized that natural adrenaline contains about 10–20 per cent of nor-adrenaline (Goodman and Gilman, 1955), a substance investigated by Barger and Dale in 1910 and strangely overlooked since.

Chemically nor-adrenaline differs from adrenaline only by the absence of the N-methyl group. There is mounting evidence that nor-adrenaline is the adrenergic transmitter substance at synapses, and not adrenaline as previously supposed. The hormone normally produced by the suprarenal medulla is, however, chiefly adrenaline. These considerations entail "a certain reorientation of our ideas on the functioning of this system. Perhaps the most important inference is that the sympathetic nervous system and the suprarenal medulla . . . should be considered as separate entities from the functional point of view" (von Euler, 1954).

Some of the contrasted effects of adrenaline and nor-adrenaline are summarized in the following table (largely based on Funkenstein *et al.*, 1952, and Goldenberg *et al.*, 1950).

TABLE XVII.14
CONTRASTED EFFECTS OF ADRENALINE AND
NOR-ADRENALINE

Cardiovascular system	Adrenaline	Nor-adrenaline
Blood-pressure	+++	+++
Pulse	+++	= or (–)
Cardiac output	+++	= or (–)
Peripheral resistance . .	(–)	+++
Metabolized in body . .	Quickly	Slowly
Effect on blood sugar . .	+++	+
Effect of Mecholyl . . .	Neutralizes	Neutralizes for a short time
Stimulation of anterior pituitary to secrete ACTH . .	+++	0
Stimulation of C.N.S. . .	+++	+
Effect of ergotamine . . .	Diminishes effects	Nil

+ = increase
0 = no change
– = decrease

The effects on the brain of these, and other, substances have recently been studied using a new technique (Feldberg and Sherwood, 1954*a* and *b*; Feldberg, 1955; Sherwood, 1955). The drugs are injected through an intraventricular cannula screwed into the skull where it may be kept for prolonged periods. This has been used in cats and in schizophrenic patients.

Nor-adrenaline and adrenaline in doses of less than 100 µg produced a condition resembling light Nembutal anaesthesia. This is presumably due to the stimulation of the region of the *massa intermedia* which Hess has shown to be concerned with sleep. (If dyes were injected in a similar manner, it might be easier to ascertain exactly where the injection substances reach.) A few microgrammes of acetylcholine injected in this way into the cat's lateral cerebral ventricle produced a condition resembling an akinetic seizure, after which the cat remains subdued and stuporous.

There is normally a blood cerebrospinal fluid barrier to nor-adrenaline (Richter, 1950) and other substances can rarely, if ever, reach these regions in such concentrations. Thus, fruitful as this technique may be in the study of the nervous system, the implications for psychology are obscure.

Ax (1953) has attempted to explain the differences between fear and anger in terms of adrenaline and nor-adrenaline production. He studied the reactions of forty-three subjects to fear and anger, recording the heart rate, ballistocardiogram, respiratory rate, face temperature, hand temperature, skin conductance and the integrated muscle potential. He claimed that fear was differentiated from anger by the different pattern of the reactions, and suggested that these were respectively "similar to those produced by injection of epinephrine and nor-epinephrine. However, neither are these patterns clear-cut, nor is their relationship to these hormones. Ax's view is in contrast to Arnold's (1945, 1950); she has suggested that anger involves a strong reaction of both the sympathetic and parasympathetic branches of the autonomic nervous system, whereas fear is merely a sympathetic reaction. As yet, Ax's theory is "not supported by substantial data" (Altschule, 1954). The recent work of Funkenstein *et al.* (1957) would appear to offer some support at least.

Funkenstein (1956) has evolved a theory which relates adrenaline and nor-adrenaline to differences in behaviour. As it is based on his work using the adrenaline-Mecholyl (Funkenstein) test, which is supposed to measure "autonomic reactivity," some of the tests of this variety will be described before proceeding to his later work.

Eppinger and Hess (1910) considered that certain symptoms could be attributed to overactivity of the parasympathetic. They therefore postulated two

syndromes, sympathotonia and vagotonia, which they believed could be diagnosed on the basis of the reactions to injections of adrenaline, pilocarpine and atropine. The syndromes were supposed to have different psychological symptoms; for example, "depression, hesitation, anxiety, apathy, melancholia, liability to phobias" were attributed to the vagotonics, whereas the sympathotonics were alleged to be "impulsive, active, busy, dominating and liable to lose control over themselves" (Guillaume, 1928).

The views of Eppinger and Hess have been severely criticized (e.g. Sachs, 1936; Altschule, 1953, 1954, etc.) and there is little evidence in favour of their tests or of the idea that either the sympathetic or the parasympathetic system may predominate (e.g. Paton and Steinberg, 1956; Terry, 1953) although the work of Wenger has helped to revive interest in this subject (see Eysenck, 1959, Chapter 8; also Lacey, 1950, 1953, also Jacobsen *et al.*, 1955).

Numerous similar tests have been devised, which are reviewed by Cyvin *et al.* (1956). That of Funkenstein was originally used to predict the outcome of electric shock treatment (Funkenstein *et al.*, 1948, 1950). The method depends upon the blood-pressure and psychological reactions to (1) mecholyl and (2) adrenaline. Several patterns of response (I to VII) have been distinguished, according to the time for re-establishing homeostasis, and whether anxiety has been precipitated. These patterns are not specific for any diagnostic category but it is claimed (1950) that prediction of the clinical response to electric shock treatment made on the basis of the physiological reactions is more reliable than the prediction made on the basis of any single diagnostic category or group of diagnostic categories.

Funkenstein *et al.* (1952) gave the standard dose of Mecholyl intramuscularly to sixty-three patients, mostly psychotic, with raised blood-pressure. They distinguished two main patterns of response, *A* and *B*, illustrated in Fig. 17.8.

The majority of group *A* were improved by E.C.T. (thirty-nine out of forty-two), whereas a large majority of group *B* were not improved (eighteen out of twenty-one). The explanation was put forward that there was excessive secretion in group *A* of an adrenaline-like substance, and in group *B* of a nor-adrenaline-like substance. (The predominant diagnostic categories in group *A* were depressions and "involutional psychoses," and in group *B* schizophrenics.)

Funkenstein and his colleagues (e.g. Funkenstein *et al.*, 1951; Funkenstein, 1956) have also found evidence that the prognosis, irrespective of treatment (whether by insulin, lobotomy, psychotherapy) is better for Group *A*.

Evidence in favour of the Funkenstein test has been

obtained by Brothers and Bennett (1954), Alexander (1955), Moriarty (1956) and Geocaris and Kooiker (1956), but Sloane and Lewis (1956) were unable to confirm its value for prognosis, and Montagu and Davies (1955) concluded that the reaction to adrenaline was of no use in prognosis. The studies by Alexander (1955) and by Sloane and Lewis (1956) appear to have been carefully carried out and the results of both were evaluated statistically: the fact that one largely confirmed and the other failed to

FIG. 17.8. TWO TYPES OF SYSTOLIC BLOOD-PRESSURE REACTIONS FOLLOWING THE DRUG MECHOLYL

On the left is a typical Group VI reaction interpreted on the basis of previous research as indicating excessive secretion of an epinephrine-like substance. On the right is a typical Group II-III reaction interpreted on the basis of previous research as indicating excessive secretion of a nor-epinephrine-like substance (From Funkenstein, 1956)

confirm Funkenstein's findings is therefore difficult to explain. Although Funkenstein *et al.* (e.g. 1952a) have emphasized that raised blood-pressure is a necessary condition for the test (and they found that only one hundred out of five hundred and eight patients were suitable subjects) this cannot explain the findings of Alexander (1955) or those of Brothers and Bennett (1954) as there was no special selection exercised, consecutive patients being tested.¹ An incidental finding in comparing five studies is that those who obtained evidence in favour of the Funkenstein test reported higher recovery rates than those who failed to confirm it.

Funkenstein and his co-workers (Funkenstein *et al.*, 1954, 1957; Funkenstein and Meade, 1954; Funkenstein, 1955, 1956; King and Henry, 1955) have carried out several studies on normal subjects under stress and on patients, which suggest that the direction of anger is related to adrenaline and nor-adrenaline, anger directed outward being associated with excessive secretion of a nor-adrenaline-like substance, whereas anger directed inwards and anxiety are supposed to be associated with excessive secretion of an adrenaline-like substance. Funkenstein (1955) wrote: "Standing

¹ It does not appear that Funkenstein rejected those with low or normal blood-pressure in his earlier studies. Moreover, if the test can only be applied to less than 20 per cent of the patients, as in his 1952 study, this must somewhat limit its value.

on the shoulders of Cannon and Freud, we have extended our view of human behaviour and discovered fertile new fields for exploration." The main characteristics which are supposed to be associated with the two different types of response to Mecholyl (shown in Fig. 17.7) are summarized in Table XVII.15.

TABLE XVII.15
FEATURES ASSOCIATED WITH THE DIFFERENT
RESPONSES TO MECHOLYL, ACCORDING TO
FUNKENSTEIN (1956)

Response type to mecholyl	A	B
	Marked fall of B.P., large area under curve, failure to return to pre-injection level within 25 min	Minimal fall of B.P., small area under the curve, rapid return to pre-injection B.P.
Funkenstein grouping	VI	II, III
Predominant secretion	Adrenaline-like	Nor-adrenaline-like
Direction of anger	Outwards	Outwards
Anxiety	May be present	Absent
Type of patient	Depressed	Angry paranoid
Stage of development in man	Relatively late	Characteristic of an early stage of development
Central sympathetic reactivity	Decreased	Normal or increased
Prognosis	Good response to E.C.T., insulin, lobotomy, and more spontaneous remissions and recoveries with psychotherapy	Poorer response to treatment
Social class	"Upper upper" (Old New England family)	Mixed

Although the terms *adrenaline-like* and *nor-adrenaline-like* are used, Funkenstein (1956) reports that Elmadjian, Hope and Freeman have confirmed, by means of a bioassay method, that the Mecholyl reaction is "an indicator of the type of preponderant adrenal medullary secretion." "Evidence of excessive secretion nor-epinephrine and epinephrine can be found in both psychotic patients and in healthy subjects, but there is a difference," namely that "in the healthy subjects, excessive secretion is found only when the subject is under stress."

Although the Mecholyl test has been interpreted by Gellhorn (*Physiological Foundations of Neurology and Psychiatry*, Chapter 20, 1953; see also Schneider, 1955) on the basis of his experiments on cats, as measuring central sympathetic reactivity, Altschule (1953) considers that tests of this kind do not measure the reactivity of the autonomic nervous system but merely "the activity of enzymes that inactivate or destroy the drugs; the reactivity of the end organs . . .; and, in the case of acetylcholine, the reactivity of some autonomic ganglia" (cf. Hoffer, 1954). Cyvin *et al.* (1956) who have studied the effects of adrenaline

and mecholyl on the intra-arterial blood-pressure (recorded from a punctured femoral artery by means of a Ludwig's kymograph) have also cast doubt on the Funkenstein test. Nevertheless, there appears to be a considerable amount of evidence in favour of the Mecholyl test and of some of the interpretations which have been placed upon it although these can only be provisionally accepted until confirmed by further experiments utilizing bioassay or fluorimetric methods. If the distinction between reaction types *A* and *B* is confirmed, it would be of interest to discover whether dysthymics (and introverts) were to be found in group *A*, and hysterics (and extraverts) in group *B*.

THE BLOOD LEVELS OF ADRENALINE AND NOR-ADRENALINE IN DIFFERENT CONDITIONS

It is only recently that it has become possible to estimate the amount of adrenaline and nor-adrenaline in the blood or urine. To be able to do this is obviously of considerable importance in assessing the psychological effects of these substances, e.g. to confirm or refute Funkenstein's theory. There are two main methods, biological assay and fluorimetry. Unfortunately these have sometimes resulted in widely discrepant results. Minute amounts, even one part in fifty-five million, can be detected.

A relationship between different emotions and changes in the blood has been shown by various methods of biological assay (e.g. Gagnon, 1952; Diethelm *et al.*, 1945; Fleetwood and Harrington, 1951; Fleetwood and Diethelm, 1951; Fleetwood, 1956). Fleetwood and Diethelm (1951) made repeated observations on twenty-six alcoholics whose psychological states were assessed independently by one author, while the other determined the amounts of adrenergic and cholinergic substances in their blood (the method of bioassay depending upon the contraction of the rabbit's duodenum, or the rat's colon and uterus, quantification being by comparison with the effects of adrenaline, nor-adrenaline and acetylcholine).

In states of *anxiety*, they found evidence of increased adrenergic substances, resembling nor-adrenaline, whereas in states of *tension* and *resentment* cholinergic substances were found. They claimed that "alcoholic patients had varying degrees of resentment when an urge to drink was present. Alcohol relieved the resentment and the corresponding substance in the blood declined or disappeared." (Alcohol *in vitro* did not have the same effect on the preparations.) They maintained "There are no indications that the resentment in alcoholic patients is different from that presented by other subjects." However, Fleetwood (1955) who studied a larger group of subjects, and used various drugs as well as alcohol, found that non-alcoholic patients showed considerably less resentment

than alcoholics did, that they had correspondingly less of the "resentment substance" and that "the effect of alcohol on the 'resentment substance' in non-alcoholic patients was doubtful. . . ." Amytal was claimed to be more effective than alcohol in relieving tension in non-alcoholics.

Ritchie (1951) has criticized Fleetwood's technique

and has failed to confirm that there is a correlation between the emotional state and the effects of the blood, and it is certainly surprising that nor-adrenaline rather than adrenaline should be the substance supposed to be related to anxiety. Independent confirmation, e.g. using fluorimetric methods, will be necessary.

HALLUCINOGENS

The drugs which have been discussed so far have recently been overshadowed by the drugs to be discussed in this and the next section, namely the hallucinogens and the tranquillizers,¹ the study of which is often equated with "psychopharmacology." The two groups of drugs tend to have opposite effects, the hallucinogens making normal subjects appear psychotic, while some of the tranquillizers tend to reduce psychotic symptoms.)

Although a great variety of drugs can cause toxic psychoses, delirium (with dissociation for place and time) is usually a marked feature. The hallucinogens, on the other hand, produce symptoms which are more like those which are found in the functional psychoses. They are therefore sometimes referred to as *psychotomimetic* or, because of their effects on imagery, *phantastica*.

Mescaline

The first hallucinogen to be studied at all thoroughly was mescaline, one of the alkaloids which were isolated by Lewin (1888) from the *Lophophorus cactus* (*Anhalonium Lewinii*). The sliced-off tops of the cactus (mescal buttons or *peyote*) have long been used by the American Indians in the region where the cactus grows, which is in North Mexico and on either side of the Rio Grande.

There have been innumerable reports on the effects of mescal buttons and of mescaline. Weir Mitchell (1896) in U.S.A. and Havelock Ellis (1897) in this country were among the first to describe their experiences with it. A few hours after taking the drug, Weir Mitchell found himself "deliciously at languid ease" and when he went into a darkened room was "enchanted" by a display such that he found it "hopeless to describe in language" which could convey to others the "beauty and splendour" of what he had seen. He supplied William James with a supply of mescal buttons, but after taking one William James was violently sick for twenty-four hours (Klüver, 1928).

During the next fifty years numerous reports of the effects of mescaline appeared, largely based on minute self descriptions by sophisticated volunteers. The

work is summarized in English by Klüver (1928), in French by Routier (1927) and, at greater length, in German by Beringer (1927). An excellent description which appeared more recently is that of Stockings (1940; *see also* Guttman, 1936). For a full description of the symptoms, reference must be made to these works.

The visual phenomena have received the most attention and certain features recur in many of the studies. For example, Knauer and Maloney (1913), who investigated mescaline at Kraepelin's instigation, found that there was a characteristic sequence of the visions which began as wavy lines and mosaics and gradually became more clearly structured, so that monuments, panoramas and finally coherent scenes representing episodes appeared (*see also* Klüver, 1928, 1942). Various other phenomena have been described such as binocular diplopia or polyopia, dysmegalopsia, metamorphopsia and dysmorphopsia. The visions are chiefly noted when the subject is in the dark or closes his eyes; with his eyes open, objects may appear to move and to be of different shapes.

"The outward behaviour of the subject acutely intoxicated with mescaline is relatively normal" (Mayer-Gross, 1951). Euphoria or anxiety may be present. Aldous Huxley (1956) pointed out at an American Psychiatric Association meeting that the classic descriptions of mescaline experiences differed from those based on patients in that they were not coloured by fear of anxiety or by the subject's personal memories but were characterized by "profound impersonality."

Concerning the state of consciousness, Mayer-Gross (1951) writes "It is difficult to classify the state of consciousness during intoxication which allows such full self-observation and at times seems to foster detachment and self-scrutiny. At other times the same subject seems to have lost all clarity of consciousness, is drowsy and even close to a state of sleep."

The main effects which have been observed are listed in Table XVII.16 (from Osmond and Smythies, 1952).

Although mescaline was considered a useful research tool for the psychologist and psychiatrist, few experiments guided by any hypothesis appear to have

¹ In most American writings *tranquillizer* is spelt *tranquilizer* but the spelling *halucinogen* has not yet been encountered.

been carried out during this period, apart from Klüver's work on the effects of mescaline on eidetic images (Klüver, 1926, 1942).

The symptoms of mescaline intoxication were often compared with those of schizophrenics. "After seeing some mescaline psychoses every investigator is at first struck by their similarity to schizophrenic states, but

with more experience is disappointed when he notices the great difference" (Guttman and Maclay, 1936). Schizophrenics can usually differentiate mescaline hallucinations from their endogenous ones, but tend to lay the blame for them on the same persecutors as before (Mayer-Gross, 1951; *see also* Denber and Merlis, 1955). One symptom which apparently does not occur in schizophrenia is synaesthesia (e.g. when a sound of hammering is accompanied by dots of colour).

In 1952 Osmond and Smythies drew attention (1) to the similarity of the chemical formulae of mescaline and adrenaline, and (2) to the similarity between *acute* schizophrenia and mescaline intoxication. They hypothesized that a mescaline-like (or M) substance was responsible for the genesis of schizophrenia. They argued that it was misleading to compare sub-acute or chronic schizophrenic reactions with the laboratory observations of trained psychiatrists taking mescaline. Although the symptoms of mescaline intoxication and of acute schizophrenia are both very diverse, "the remarkable thing is that these acute reactions have so much in common" (*see* Table XVII.16).

Although Stockings (1940) had suggested that "a toxic amine with chemical and pharmacological properties similar to those of mescaline" was the causative agent of psychoses and de Jong had pointed out the similarity of adrenaline and mescaline (1945), the implications had never been followed up.

The search for the M substance was begun in conjunction with Hoffer (1954) and it was claimed that adrenochrome, a derivative of adrenaline, induced psychotic phenomena in normal subjects, the main symptoms being overactivity, depression, hallucinations and loss of insight. Rinkel *et al.* (1954) were unable to confirm these findings and suggested (Rinkel *et al.*, 1955) that adrenoxine was the effective substance.¹ Meanwhile, Hoffer and Osmond (1955) suggested yet another oxidation product of adrenaline, adrenolutin (*see also* Hoffer, 1957). Both adrenochrome and adrenolutin have indole nuclei.

Lysergic Acid Diethylamide

Meanwhile another compound, also having an indole nucleus, was being investigated, namely lysergic acid diethylamide (LSD). It is a semi-synthetic derivation of ergot, and was accidentally found to have hallucinogenic properties by the chemist Hoffmann, in 1943. Its psychological effects were first reported by Stoll (1947, 1949). Unlike mescaline, it is active in minutely small quantities (25–50 µg), but the psychological effects are rather similar, although, for example, Matefi (1952) claimed that they were

¹ Rinkel *et al.* used the inert semicarbazone of adrenochrome, not adrenochrome itself.

different. (Cf. Hoch, Cattell and Pennes, 1952; Frederking, 1955.)

There has already been a large amount of work done on LSD, and a bibliography by Cerletti (1956) lists one hundred and thirty-seven references, and a more recent one, provided by Sandoz, two hundred and fourteen. In a brief account, it is extremely difficult to select appropriate items for discussion as such a vast range is covered, from the effects of LSD on the Siamese fighting fish (Evans *et al.*, 1956), on the visual system of the cat (Evarts *et al.*, 1955), the neuroses (Sandison, 1954), the metabolism of separated mammalian cerebral tissues (Lewis and McIlwain, 1954), its affinity for wool (Fischer, 1954), to its effect on snails (Abramson and Jarvik, 1955), and on artistic expression (Tonini and Montanari, 1955). To bring together the conclusions of such disparate studies would require a longer account than can be given here. Much of the recent work is summarized by Marrazzi, Hart and Cohn (1956). For clinical reports, see Savage (1955), Anderson and Rawnsley (1954), Forrer and Goldner (1951), Sandison *et al.* (1954), Hoch *et al.* (1952), etc.

Comparatively few psychological studies have been carried out on the effects of LSD. Sloane and Doust (1954) used a variety of tests on normal subjects and on psychiatric patients, but concluded that "it proved difficult to obtain valid differentiating measures of clinically apparent changes." For example, in spite of "the subjective impressions of distractibility and intoxication" there were no significant changes in the tests of concentration and memory. However, Landis and Clausen (1954) give some evidence of impairment of performance on psychomotor tests by early schizophrenics who were given LSD or mescaline, but their groups were too small for "the normal tests for statistical significance" to be applied.

The most intensive studies of the psychological and other effects of LSD have been carried out by Abramson and his co-workers. So far some twenty-five articles have appeared. Some of the findings would be easier to assess if it had been practical to describe some of the experiments in a single account. "Research which can be described and published most efficiently in one unit should generally be so published, where this is practical, rather than be fractionated for multiple publication in a variety of media" (*APA Ethical Standards of Psychologists*, 1953, principle 5.34-2). It is to be hoped that a single comprehensive publication covering the entire research will eventually be published.

There is one other general criticism of the research which should be mentioned, namely that the LSD was given in tap-water instead of distilled water, as the former may contain substances which reduce or inactivate the LSD. In a personal communication

Abramson (1957) writes: "We have done many experiments on the effect of various vehicles on the administration of LSD-25 and it is rather difficult to inactivate LSD-25 unless strong oxidizing agents are present in quantity." However, Hofmann, the chemist who discovered the psychological effects of LSD disagrees with this statement as, if "25 gamma of LSD-25 are dissolved in 20 ml of tap water, a chlorine content of 1 part in 2.5 million will be sufficient to immediately destroy all the LSD," according to a personal communication from Holgate (1957). The tap water may, of course, be free from any halogen, but if it is not its use inevitably casts doubt on any quantitative relationships between dose and effect and raises the suspicion that some of the supposed drug effects may be *placebo* effects and that when effects fail to occur, it may be that the water had just been chlorinated.

In studies I and XV (Abramson *et al.*, 1955) the effects on normal subjects of varying doses of LSD and of tap water were studied by means of a questionnaire. After the *placebo*, moist palms, headache, drowsiness, anxiety, etc. were the commonest symptoms and the greatest number was recorded within half an hour of ingestion of the *placebo*. After 50 μ g LSD, "unsteadiness, dream-like feelings, funny feelings on the skin, inner trembling" . . . , etc. were recorded, the peak effect occurring between one and a half and two and a half hours after ingestion of the drug.

There are seven separate articles devoted to the psychological effects of LSD (IV to X). In each of these studies, six males and six females took part, and it appears that there were the same subjects for each of the experiments.

Tests were administered at four separate testing sessions, separated by at least a week. On the first occasion the subjects received a *placebo*, tap water, and on the second and third, 50 and 100 μ g respectively of LSD-25; on the fourth occasion a *placebo* was given once again, in order to measure the effects of repeated testing. Nevertheless, the design of the experiment does not make it easy to measure the extent of the practice effects in the drug sessions.

The functions studied included attention and concentration (Jarvik *et al.*, 1955), spatial relations abilities (Abramson *et al.*, 1955), recall and recognition of various stimuli (Jarvik *et al.*, 1955), motor performance (Abramson *et al.*, 1955), arithmetic test performance (Jarvik *et al.*, 1955), reaction-time to auditory and visual stimuli (Abramson *et al.*, 1955).

Simple and complex cancellation tests were used as tests of attention and concentration. Six out of eight tests showed no significant change when scores of the pre-LSD-25 zero sessions were compared with the 50 μ g scores. Two tests, cancellation of "a"s and

vowels showed significantly impaired performance when zero and 100 μ g were compared. Cancellation of words showed a significant improvement under 100 μ g of LSD. With two exceptions there was a significant increase between the first and the fourth sessions and the score decreases under the drug would probably have been more significant if the practice effect had been allowed for.

The Thurstone Hand Test and Minnesota Paper Form Board Test were used as tests of special relations. LSD-25 tended to impair the scores on these, but only a few of the changes were significant.

Nine tests of recognition and recall were used, equivalent forms being employed in the different sessions. It was found that 100 μ g of LSD-25 significantly impaired the performance on six of the nine tests, compared to the placebo, whereas the 50 μ g dose had no significant effect.

Digit span and nonsense syllable recognition showed no significant changes under the drug.

Neither the pursuit rotor test nor the steadiness test showed any significant differences between the zero dose scores and the drug scores, nor between the two drug scores, although there was a tendency for increasing impairment with increasing doses.

The arithmetic test, which involved a number of problems consisting of three numbers and required two operations to be performed appeared to one of the more sensitive tests in the battery for detecting the presence of LSD-25. It was most consistently and significantly impaired, and it was considered that LSD-25 impairs abstract thinking, ability to concentrate, and the ability to recall in normal adults.

On the average, the manual reaction-time tests were not sensitive to the drug, whereas the verbal reaction-time tests were significantly impaired, the reaction-time being longer the higher the dose.

Another test which might be mentioned here is the Bender-Gestalt test, although this was done by another group of twenty-six subjects (Abramson *et al.*, 1955). A standardized quantitative scoring system designed to differentiate psychiatrically ill persons from normal subjects was used to score the performances. There was a tendency, under the influence of the drug, for change to occur in a direction so as to resemble more closely the scores of psychiatric in-patients and out-patients. However, "the number of individual experimental subjects who shifted to predominantly or specifically psychotic modes of responding to the test stimuli was not sufficient to demonstrate statistically, in so far as the Bender-Gestalt scores furnish a measure of such change, that LSD-25 in such doses precipitates experimental psychotic-like states comparable to clinical psychotic reactions."

Using very large doses (up to 200 μ g) of LSD, they found that there was impaired performance on the

Wechsler-Bellevue intelligence test (Levine *et al.*, 1955).

As a result of a content analysis of the symptoms described in one hundred and forty-one experimental sessions on thirty-one subjects with LSD, Abramson *et al.* (1955) concluded: "Neurotic signs do not correlate with the magnitude of dose, while psychotic signs and distortions in perception do correlate with the magnitude of the dose." Using the category system devised by Bales they studied the effects of LSD on group communication; the drug tended to reduce the output of words of those who had received the drug, while the members of the group who had not received the drug increased their output. "The ratio of questions to answers, as well as the ratio of orientation to evaluation responses, is higher in the group under the condition 'LSD-25' than under condition 'normal'" (Lennard *et al.*, 1955).

Personality changes were assessed by various tests including the Rorschach, word association test and parts of the Thematic Apperception Test. There was a significant increase in M, an increase in the M and decrease in the FM in the M:FM ratio, an increase of Dd, increased in H, and a decrease in W and increase in M in the W:M ratio (as scored by Brown's modification of Klopfer and Kelley's method). It appears that these tests were carried out in the same session as the Wechsler-Bellevue, already reported, when very large doses were given. Five of the twenty-one subjects "showed a reaction which closely resembled paranoid schizophrenia" (Levine *et al.*, 1955b). Changes in handwriting after LSD were variable (Hirsch *et al.*, 1956). The remaining studies deal with the development of tolerance to LSD (Abramson *et al.*, 1956), the effect of transference (Abramson, 1956), "ego enhancement" (Abramson, 1956), and also psychotherapy (Abramson, 1955).

Other studies of normal subjects under LSD, in which psychological tests have been used are those of Rinkel *et al.* (1952 and 1955), de Shon *et al.* (1952), Bercel *et al.* (1956a and b), von Felsinger *et al.* (1956). As with mescaline, dilatation of the pupils is a constant sign and there are various autonomic changes. Visual illusions, hallucinations and other abnormalities may occur, including synaesthesiae. The time sense is distorted and the "ego boundaries" were disturbed. Euphoria or anxiety may occur and also sexual stimulation, which has rarely, if ever, been reported to occur with mescaline. Von Felsinger *et al.* (1956) report that there is "a slowing down of speech and expression." They also found that the relationship between personality and the reaction to LSD was not as marked as with certain other drugs, but they claimed that there was a correlation between the amount of induced change and the degree of pre-existing maladjustment (in ten subjects) (but cf.

Abramson *et al.*, 1955). There is probably a similar relationship of personality to drug effect as is observed with mescaline (e.g. Guttman and Maclay, 1936), although Beringer (1927) was unable to establish any such relationship.

There has been controversy as to whether the LSD-induced state resembles schizophrenia, as with mescaline. There are those in favour of the resemblance (e.g. de Shon, Rinkel and Solomon, 1952; Savage and Choldon, 1956), and those against (e.g. Hoch, Cattell and Pennes, 1952; Ebaugh, 1955; von Felsinger *et al.*, 1956). The psychological test results are of very little help in resolving this controversy, Hoagland, Rinkel and Hyde (1955) have found some biochemical evidence in favour of the similarity which, in conjunction with their previous studies (Rinkel *et al.*, 1952, 1954, 1955a and b) suggested that "an endogenous derivative of epinephrine metabolism may act in the schizophrenic patients after the manner in which LSD acts in normal persons."

Thus the work both on mescaline and on LSD converges on the adrenaline metabolism of schizophrenics (*see* Fischer, 1954; Hoffer and Osmond, 1955; Hoffer, 1957; Lea, 1955; Cowden, 1957).

Although the effects of large doses of mescaline are similar to those of minute doses of LSD, the two substances are chemically dissimilar, but it has been suggested (Fischer, 1955; cf. Jarvik, 1956), that mescaline is transformed into a substance resembling LSD before it takes effect. It would thus acquire an indole nucleus which, as Woolley and Shaw (1954) pointed out, is common to several hallucinogens such as haomine and yohimbine. They argued that these substances were antimetabolites to serotonin (5-hydroxytryptamine or 5-HT, a substance whose distribution in the brain is similar to that of adrenaline and nor-adrenaline (Amin *et al.*, 1954). Wooley and Shaw postulated that LSD might induce a serotonin deficiency and also that "naturally occurring psychiatric states such as schizophrenia might well be pictured as resulting from a deficiency of serotonin in

the brain," or possibly from an excess. The discovery by Brodie *et al.* (Shore, Silver and Brodie, 1955) that reserpine causes a release of serotonin from the brain of the rabbit appeared to link up the actions of hallucinogens and tranquillizers. However, as chlorpromazine has a reserpine-like effect but does not liberate 5-HT and, as BOL antagonizes 5-HT as markedly as LSD but does not produce any mental disturbance (Cerletti and Rothlin, 1955) this hypothesis is probably untenable.

The mode of action of hallucinogens is still a matter of speculation. According to one theory, they act by inhibiting cholinesterase or pseudocholinesterase (Thompson *et al.*, 1955; Hoffer, 1957). Another view is that they interfere with cerebral synaptic transmission: Marrazzi and Hart (1955b) argue "that cerebral synaptic transmission plays a part in the action of hallucinogens and other inducers of chemical psychoses of endogenous or exogenous origin, either by the direct disruption of normal patterns of synaptic activity responsible for behaviour, or indirectly by inhibiting normal restraints and thereby releasing aberrant patterns of activity as a result of alteration in the normal balance between cholinergic excitation and adrenergic inhibition at susceptible cerebral synapses."

Since hallucinations are often visual, they investigated the effects of various compounds on the transmission of impulses from the transcallosal system to the visual cortex of the cat. Adrenaline, adrenochrome, serotonin, bufotenine, amphetamine, mescaline and LSD were tested, and all produced varying degrees of inhibition of synaptic transmission. When ranked in order according to their effectiveness in this respect, it was found that this corresponded with their clinical effectiveness in producing hallucinations. Using mescaline to inhibit the evoked response in the transcallosal system of the cat, they also found that the inhibition could be reduced by chlorpromazine, reserpine and Frenquel (Marrazzi, Hart and Cohn, 1956, pp. 571-2, 574, 578).

TRANQUILLIZERS ✓

It has yet to be shown that the various substances marketed as "tranquillizers" have enough properties in common to justify grouping them together. In theory, they are supposed to calm without inducing confusion or sleep. Some, such as chlorpromazine and reserpine (or compounds related to them) may retain a place in psychiatric treatment, but the other "tranquillizers" have been introduced too recently to justify their discussion here: should they prove to be effective this would stimulate numerous studies on them which would soon make any account written

now out of date, whereas their failure to justify the claims of their manufacturers would make such an account superfluous.

It is notorious that certain wines are ruined by being brought to this country. Sargent writes (1956): "In this respect one can expect fewer reports of good results from reserpine and chlorpromazine in this country than in the U.S.A. and France, because most of the patients are already receiving skilful treatment." Similarly, "an interesting if somewhat tendentious explanation of why American reports of the effects of

tranquillizers such as reserpine are so much more enthusiastic than experience in British Hospitals would justify" is that mental hospitals in the U.S.A. have been understaffed and "their psychiatric outlook has been dominated by psychoanalytical ideas. . . ." "In consequence the American chronic mental patient has been in a state of greater neglect and the improvement he has shown when someone has taken an interest in him, and even given him a few new tablets, all the greater" (*Annotation Brit. Med. J.*, 1956).

There are four main groups of tranquillizers—

1. *Phenothiazine derivations*, e.g. chlorpromazine (Largactil, Thorazine, Megaphen), promazine (Sparine), percazine (Pacatal), etc.

2. *Rauwolfia alkaloids* (of which reserpine (Serpasil, Sandvil, Quiescin) is the best known).

3. *Benzhydrol derivations*, e.g. hydroxyzine (Atarax) benactyzine (Suavitol, Nutinal, Ludicil, Parasan and Cevanol), azacyclonal (Frenquel).

4. *Compounds related to mephenesin*, i.e. Meprobamate (Miltown, Equanil, Mepavlon) (Berger, 1957).

The main indications for tranquillizers are in the treatment of chronic agitated, excited or aggressive psychotics who can thus be subjected to chemical rather than physical restraint. Chlorpromazine appears to be more effective than reserpine, but it is not possible to predict, e.g. according to diagnosis, which is more likely to be effective. Both are liable to produce undesirable side effects; for example, chlorpromazine may cause jaundice, agranulocytosis, orthostatic hypotension, hypothermia, dryness of the mouth, photosensitivity, tachycardia, etc., whereas reserpine may result in nasal congestion, drowsiness, hypotension, nausea, vomiting, increased body weight and depression sometimes leading to suicide. Both can induce a Parkinson-like syndrome. Neither has been found to be of much use in the treatment of out-patients in this country, nor have the tranquillizers such as Meprobamate and benactyzine proved to be very effective in their treatment.

It remains difficult to explain why the use of tranquillizers by non-hospitalized patients in the U.S.A. should be criticized as seducing them into a bogus health (Cobb, 1957) and "a threat to American society" (Dickel and Dixon, 1957). It may partly be due to advertising: "Never has advertising reached such volume, such incessant repetition, nor such telling suggestions by word and picture" (Cobb, 1957). Whatever the reasons may be, the effects of tranquillizers on out-patients in this country have been remarkably unimpressive. For example, Raymond *et al.* (1957) compared amylobarbitone, benactyzine, chlorpromazine, Meprobamate, Sedaltine (a concoction including rauwolfia alkaloids) and a placebo, on

over fifty neurotic out-patients who had a "tension component in the symptomatology." Each patient received each drug for a fortnight, the drugs being given by the "double blind" method and the design being based on a Latin square. The patients recorded daily the effect of the drug on a 5-point scale. The cheapest, and also the smallest and least impressive of the tablets of amylobarbitone were the only ones found to be significantly superior to the placebo which had an average score close to zero.

Folkson and May (1955) and McGrath *et al.* (1956) found reserpine of little value in neurotics, but Davies and Shepherd (1955) and also Fergusson (1956) found some evidence in its favour in this connexion, although the latter was unable to find significant improvement in ten tests of anxiety. That deteriorated chronic psychotics may benefit from reserpine has, however, been confirmed in this country (e.g. Glynn, 1955; Wing, 1956; Foote, 1955; Moore and Martin, 1957), but chlorpromazine appears more effective and to have fewer side-effects (Vaughan *et al.*, 1955). Lomas (1957) compared Pacatal (percazine) with chlorpromazine in schizophrenics, and concluded that there was nothing "to suggest that Pacatal has any value in the treatment of a mixed group of schizophrenic patients." Thorpe and Baker (1956) also found it inferior. Lieberman and Vaughan (1957) and Coady and Jewsbury (1956) found benactyzine had no effect on muscle tone and it gave no significant relief of symptoms; similarly Seager and Leitch (1956) found no evidence that it was of use, although Davies (1956) found that it appeared to benefit some patients.

In this country only the original tranquillizers—chlorpromazine and reserpine—have an established use, and the status of the others remains controversial. Interesting reports have been published on the effects of Meprobamate on driving tests, etc. (Marquis *et al.*, 1957), conditioned fear (Hunt, 1957), and "imprinting" in the water fowl (Hess, 1957). These are too recent to make possible any thorough-going appraisal, but suggest the worth-while of persevering with research on this drug. (Cf. also Eysenck *Experiments in Personality*, to be published.)

A large number of animal experiments have been done using chlorpromazine and reserpine. These drugs have been found, for example, to cause a reduction of hostility and sociability respectively in the cat (Norton and de Beer, 1956), and reserpine results in a decrease in conditioned avoidance responses in the monkey (Smith *et al.*, 1956; and Weiskrantz and Wilson, 1955) and in the rat (Brady, 1956; see also Sidman, 1956). Guha *et al.* (1954) found chlorpromazine relatively more effective than reserpine in decreasing the performance of a conditioned reflex in rats, and Cook *et al.* (1955), who found that chlorpromazine was effective in reducing spontaneous or

d-l-amphetamine-induced activity in mice, confirmed that this drug tended to block a conditioned response in rats (*see also* Killam *et al.*, 1956; Rutledge and Doty, 1955).

Few tests have been carried out on human subjects receiving these drugs. Petrie and Le Beau (1956) claimed that chlorpromazine caused a decrease in neuroticism and an increase in introversion (the latter in contrast to leucotomy patients), but Porteus (1957) using his maze found that there was a drop in score, as after leucotomy. Several studies have utilized

psychological tests or rating scales (e.g. Gaitz *et al.*, 1955; Gardner *et al.*, 1955).

Perhaps this brief and somewhat sceptical account has done less than justice to the latest "new era" in psychiatry. The reader may like to judge after consulting a recent paper by Little (1958), containing an account of a well-controlled "double-blind comparison of the effects of chlorpromazine, barbiturate and a *placebo* in one hundred and forty-two chronic psychotic in-patients." There were no significant differences between the three treatments!

GENERAL SUMMARY

The data are too divergent to permit of any useful kind of summary. With the exception of the dimensional hypothesis outlined at the beginning, little in the way of general descriptive or causal relationship between personality and drug effect has emerged. Few results have been found which stood up to replication of experiments, and few findings have achieved the status of facts on which future works may build. The reasons for this sorry state of affairs are obvious. Enthusiasm in research is no compensation for lack of competence, and few workers in the field have had the requisite training in psychological research methodology, statistical knowledge, biochemical expertise and general physiological know-how to avoid quite elementary errors. Co-operative effort is improving the situation, but worth-while theories seldom issue from committees. Nevertheless, the promise, both for research and for applied work, held out by drugs is such that a rapid advance is likely to take place—the first for years. Of all the chapters in this book, this one is the most likely to be out of date, if any, when a new edition is called for.

CHAPTER 18

The Effects of Psychotherapy

H. J. EYSENCK

INTRODUCTION

IN theory, the study of the effects of psychotherapy should be similar in methodology and experimental treatment to the study of the effects of any other therapeutic agent about which definite theories are held. In actual practice this is not so. An emotional feeling of considerable intensity has grown up in this field which makes many people regard the very questioning of its effectiveness as an attack on psychotherapy; as Teuber and Powers (1953) point out; "To some of the counselors, the whole control group idea . . . seemed slightly blasphemous, as if we were attempting a statistical test of the efficacy of prayer . . ." When the writer (1952) published a short paper summarizing the available evidence and concluding that there was little support for those who believed in the efficacy of psychotherapy, reactions ranged all the way from Sanford's (1953) opinion that "the only wise course with respect to such a challenge is to ignore it," to Meehl (1955) who said: "I cannot agree with those who consider this a foolish question or who feel little need to meet such challenges." The considerable argument aroused by this paper (Luborsky, 1954; De Charms *et al.*, 1954; Rosenzweig, 1954; Eysenck, 1954, 1955) seems to have arisen from the conviction, well put by Shoben (1956), that "the conclusive evidence of therapeutic effectiveness must come not from argument, but from relevant and rigorous research." This chapter is an attempt to review the literature, much of which has appeared since the writer's previous review was published, in order to discover whether any new light has been thrown on this thorny problem.

To judge by their writings, some advocates of psychotherapy appear to take an attitude similar to that adopted by Galen, the father of modern medicine, in his advocacy of the wondrous powers of Samian clay: "All who drink this remedy recover in a short time, except those whom it does not help, who all die and have no relief from any other medicine. Therefore it is obvious that it fails only in incurable cases."

There are three main differences between Galen's hypothesis and that maintained by modern psychotherapists. In the first place, we have the question of *definition*. There is no disagreement about the nature of Samian clay, but as regards psychotherapy, *quot homines, tot sententiae*. In the second place there is the question of the *criterion of cure*. In Galen's case this was survival, which is easy to observe; in the case of psychotherapy, the criterion itself is in doubt, and its measurement fraught with difficulties. In the third place there is the *time factor*. Those who partook of Galen's remedy "recovered in a short time," so that the effects were easily observed; psychotherapy, particularly that of the psychoanalytic type, may go on for as many as twenty years or more, so that considerable difficulties arise in allocating responsibility for any recovery. We will now take up these points in detail, before turning to an examination of the evidence.

Definition of Psychotherapy ✓

Raimy (1950) has characterized the confusion existing with respect to the nature of psychotherapy by defining it as, "an unidentified technique applied to unspecified problems with unpredictable outcomes. For this technique we recommend rigorous training." When we turn to definitions offered in a more serious vein, we find considerable divergences. Perhaps the most inclusive definition is one given by Levine (1948) to whom "psychotherapy means therapy by psychological means . . . it means treatment applied directly to the 'mind,' by which we mean not a separate entity, but the functioning of the person as a human being. Psychotherapy includes the direct treatment of one person, as a person, by another. It includes also the indirect treatment of one person by another, through the intermediary of other persons or situations . . . in general, psychotherapy can be defined as the provision by the physician of new life experiences which can influence a patient in the direction of health."

Similar but rather briefer is Rosanoff's (1947) definition: "Psychotherapy . . . consists in the employment of mental factors in the treatment of disease," and that of Jaspers (1918): "Psychotherapie heissen alle die Behandlungs-methoden, die auf die Seele oder den Körper mit Mitteln wirken, die über die Seele führen." (As evidence of the inclusiveness of these definitions we may quote the fact that Jasper expressly mentions "gymnastics" as one of the methods of psychotherapy!) English and Finch (1954) may also be quoted here: "Psychotherapy may be defined as the art and science of treating mental and emotional disorders and diseases through changing ideas and emotions to bring about a more favourable psychic equilibrium . . . Almost any method utilised to alleviate or remove the results of emotional conflict and improve psychic adjustment may be termed psychotherapy."

Rather more restrictive and less all-inclusive are Curran and Partridge (1955), who say that: "Psychotherapy aims at relieving symptoms of psychic origin by adjusting the attitudes that have led to their development . . . The treatment proceeds by stages which are often referred to as *explanation, suggestion, persuasion* and *re-education*." Shoben (1953) is a little more specific still. "Psychotherapy is a certain kind of social relationship between two persons who hold periodic conversations in pursuit of certain goals: namely, the lessening of emotional discomfort and the alteration of various other aspects of client behaviour . . . Therapy proceeds by virtue of communication and the therapist-patient relationship, towards the goal of alleviating symptoms and increasing the patient's affective comfort and social utility."

Most restrictive of all are certain psychoanalysts and other members of specific schools who would restrict the use of the term to procedures practised by members of their particular school. Psychotherapy would then be defined in terms of a particular theoretical system giving rise to specific methods of procedure, such as the employment of transference and counter-transference, catharsis, ego-strengthening, and so forth. Hathaway (1951) has well contrasted this narrow conception with the very broad ones quoted at the beginning of this section—

With the intention of arriving at a working definition of the term psychotherapy, at least two extremes in connotation may help in orientation. The first extreme is illustrated by those few psychoanalysts who affirm that there is only one type of psychotherapy, namely, psychoanalytic therapy, and that any other approach is a covering up or ameliorative procedure not properly so considered. Although the most brash proponents of such an extreme concept of psychotherapy are probably psychoanalytic in persuasion, there are here and there

other therapists who hold analogously restricted views. At the other extreme, psychotherapy becomes almost any predominantly psychological procedure, personal or environmental, that is assumed to be contributory to mental hygiene or personal adjustment. With this broader definition, better living conditions, better food, and the like, all become psychotherapeutic procedures in so far as they have psychological implications. One might then cite a music program in a clinic or hospital as an example of psychotherapy and the staff musician as a psychotherapist. Neither of these extreme positions is here accepted as particularly useful . . . The former connotation restricts progress by encouraging doctrinal and isolated positions antipathetic to new ideas. It inhibits active experimentation by persons who might not accept the tenets of the particular procedures defined as psychotherapy. The latter is so broad as to constitute almost a statement of the general principle that simply healthy living is therapeutic.

A decision on a definition in view of these wide divergencies must obviously be arbitrary. We shall here adopt the middle-of-the-road position not dissimilar to that defined by Winder (1957), according to which a treatment is labelled "psychotherapy" when the following conditions are fulfilled—

1. There is an interpersonal relationship of a prolonged kind between two or more people.
2. One of the participants has had special experience and/or has received special training in the handling of human relationships.
3. One or more of the participants have entered the relationship because of a felt dissatisfaction with their emotional and/or interpersonal adjustment.
4. The methods used are of a psychological nature, i.e., involve such mechanisms as explanation, suggestion, persuasion, and so forth.
5. The procedure of the therapist is based upon some formal theory regarding mental disorder in general, and the specific disorder of the patient in particular.
6. The aim of the process is the amelioration of the difficulties which cause the patient to seek the help of the therapist.

Having thus defined psychotherapy in general, we may add that it may be useful in many circumstances to specify different types of psychotherapy in terms of the particular theory adopted by the therapist. This may be done most simply by adopting a system of subscripts so that psychotherapy $_{PA}$ denotes psychotherapy carried out according to the dictates of the psychoanalytic method. Psychotherapy $_{CR}$ would denote non-directive psychotherapy carried out according to the theories of Carl Rogers. Psychotherapy $_{E}$ would denote eclectic psychotherapy based on the rather less formalized theories which currently

pass as "orthodox" in psychiatric circles. Further types of psychotherapy can be distinguished, but there is little point in attempting any complete listing here. The device of indicating types of psychotherapy by the initials of the originators will retain its usefulness as long as there are sufficient letters of the alphabet to go round.

This question of definition does not, of course, settle the very difficult problem of whether the different methods we have distinguished by subscripts do *in fact* differ from each other in practice, nor does a definition tell us what does actually happen during treatment. Many attempts have been made to answer these questions, but the evidence is still so fragmentary, anecdotal and uncoordinated that a review of it at this point would serve little useful purpose (Ellis, 1955). It is impossible therefore to say whether the different types of therapy are in fact differentiated from each other in terms of the actual procedures adopted, or whether individual differences between therapists of the same persuasion are as great or greater than those between therapists of different persuasions. (For studies of therapeutic procedures, cf. Matarazzo, 1956; Saslow, *et al.*, 1955; Moustakas, *et al.*, 1955; Sommer, *et al.*, 1955; Danskin, 1955; Bordin, 1955; Eldred, *et al.*, 1954; Grossman, 1952; Rogers, 1951, 1942; Harway, *et al.*, 1955; Raush, *et al.*, 1956.)

Measurement of Outcome

When the method of psychotherapy has been applied to a group of patients, we obviously must have some measure to determine the initial status as well as the final status of the group. Many discussions of this problem have been reported by Zubin (1953), Knight (1941), Thorne (1952), Greenhill (1955), Watson, *et al.* (1951, 1952), and Miles, *et al.* (1951). In addition there are discussions in the books by Rogers and Dymond (1953) and by Mowrer (1953). We may summarize rather briefly in the following paragraphs the possible measures of outcome which may be used.

INTROSPECTIVE REPORTS

It is the patient who seeks our aid, and, obviously, his own judgement of any changes that have taken place is important. This may be obtained by interview, in the form of a freely written essay, by answers to a questionnaire, by means of Q-sorts, through a set of attitude endorsements, or in many similar ways. (Lipkin, 1954; Murray, *et al.*, 1954; Dollard, *et al.*, 1953; Gallagher, 1953.) It is obvious that the more objective the method used, the more trustworthy will the results be. Thus a questionnaire would be preferable to an essay. It need hardly be emphasized that, in making use of formal instruments, technical

competence regarding their construction and evaluation is required. This point is mentioned only because so many experimenters have failed to take into account obvious technical difficulties arising from the method of research adopted. Thus many workers have made considerable use of Q-sorts without heeding the warning given by Cronbach and Gleser (1954) in their review of this method: "It is imperative to discourage students of personality and social psychology from copying Stephenson's designs as he presents them . . . We fear that Stephenson's book (1953) may misdirect much research effort."

RATINGS

Many of the difficulties of which the patient complains are of a kind which can be observed by outsiders. Irritability, social clumsiness, hyper-emotionality and other behaviour patterns can be rated by outside observers, and such observations should always supplement the patient's own report. Ratings can be formal or informal, and may be made by psychiatrists, social workers or the patient's family, friends or workmates. Again, it need hardly be said that these ratings are more valuable the more systematic they are, and the more they pay attention to the rules laid down by psychologists on the basis of the very large body of experimental work in this field (Eysenck, 1953). If possible, the reliability of such ratings should be established, and it should not need to be emphasized that those judges who are emotionally concerned with the particular direction of change should never be the only ones to give a rating on a particular patient. (This refers more particularly to the psychiatrist in charge of the patient, who must always be suspected of favouring the positive outcome compared with a negative one.) Sociometric measures are of value and may be listed here, as they appear to be essentially similar in their nature to ratings. (Neuburger and Schauer, 1953; Rosenberg, 1954; Parloff, *et al.*, 1954.) Rating methods are discussed in Chapter I in some detail.

PERSONALITY TESTS

This is not the place to discuss the wide variety of personality tests which may be administered to the patient in order to test specific hypotheses regarding a change that has taken place; many such tests are described in other chapters of this book. It may be necessary, however, to insist that it is useless to administer a test whose reliability and validity is either low or unknown. The writer has reviewed elsewhere the literature bearing on the reliability and validity of the so-called "projective techniques" (Eysenck, 1958), and the conclusion arrived at in that review was that these tests had failed to establish their value in any of the fields in which they had been

used. Thus projective techniques should not be used as evidence to establish the outcome of psychotherapy, because any changes which might occur in the test would not be capable of interpretation. Few personality tests are characterized by a high degree of reliability and validity, but tests such as those of level of aspiration, suggestibility, and conditionability, do enable the research worker to test specific hypotheses and arrive at interpretations of his results which have a solid experimental foundation.

PHYSIOLOGICAL MEASURES

In view of the close relationship between the autonomic system and emotion, and in view also of the predominantly emotional character of so many neurotic complaints, it seems desirable that the possibility of physiological changes should not be disregarded. Much of the relevant work has been reviewed in another chapter of this book and little will, therefore, be said here about it. (Shagass and Malmo, 1954; Thetford, 1948; Di Mascio, *et al.*, 1955; Boyd, *et al.*, 1954; Bixenstine, 1955; Coleman, *et al.*, 1956.)

EXPERIMENTAL INVESTIGATIONS

The most useful type of study, in our view, is that which is specifically designed to test a clear-cut hypothesis, and it will often be found that, in order to test such a hypothesis, a special experimental set-up will have to be elaborated. Thus we may hypothesize that psychotherapy of a certain type applied to a certain group will lead to an increase in frustration tolerance. In order to test this hypothesis it will be necessary to define frustration tolerance experimentally, and to design the experiment in such a way that psychotherapy is included as the independent variable. Little has been found in the literature to suggest that this method of research, in our view much the most preferable, has been used much by research workers.

SOCIAL ACTION EFFECTS

It is sometimes possible to assess the effects of treatment by reference to certain actions taken by society in relation to the patients who are being treated. Thus, for instance, certification presents us with an example of social action which can be given a numerical value and treated statistically. In the same way, we may consider the effect of psychotherapy on psychopathic behaviour, and a record of court appearances may be of relevance in assessing the value of the therapy. Here again, considerable experience and knowledge are required to evaluate the many factors liable to mislead the investigator and invalidate his conclusions; it must be assumed that the investigator is competent in such lines of research.

Each of the six methods outlined above has its own

advantages and disadvantages. It may be a counsel of perfection to suggest that in any worth-while investigation more than one method should be used and that, preferably, all six methods should be included. The necessity for this, is highlighted in an experiment by Kogan, *et al.*, (1953), who used three reliable measures of the effectiveness of therapy (client evaluation, case reader movement rating, and distress relief quotient shifts,) only to find negligible correlations between them. As Meehl (1955) points out "such a fact should make us cautious about single 'criteria' used in the evaluation of therapeutic outcome."

One other point may require to be stressed. The effects of psychotherapy, as of most other experimental manipulations of human beings, are presumably multidimensional, and consequently research should be concerned with shifts in more than one direction. The usual habit of simply rating people as "improved" or "not improved" entirely neglects to pay attention to the important and obvious fact that "improvement" is not a unidimensional concept. Under treatment a man may lose his depression, but start beating his wife; is this to be rated as "improved" or "not improved?" It is clear that research must become much more analytic before we can find out very much about the effects of psychotherapy. Further, this belief implies that progress will become much more rapid when hypotheses regarding change become more specific. It is almost impossible to prove or disprove vague and general talk about "improvement"; specific statements are much more valuable scientifically as well as easier to investigate experimentally.

GENERAL METHODOLOGY

We have now defined what we mean by psychotherapy, and have indicated the kind of measures which might be used with advantage to study the effects of therapy. What kind of design is appropriate for studies of this kind? Hunt (1952) and Watson (1952) have considered this problem, as have Greenhill (1955), Thorne (1952), Zubin (1953) and many others. A paper by Campbell (1957) which discusses the problem from a more general point of view is perhaps the most useful. A set of minimum requirements is stated by Meehl (1955) as follows: "The minimum standard for an adequate outcome study obviously includes (a) a control group, (b) pre- and post-therapy evaluation procedures which are either 'objective' or, if judgemental, are uncontaminated, (c) follow-up of both groups, preferably repeated so that exacerbation and remission rates can be estimated and the curves extrapolated." Meehl goes on to say: "I am saddened to report that perusal of over two hundred journal articles and a dozen books reveals one paper

approximating these desiderata (relaxing requirements by forgetting follow-up but insisting upon controls does not change this figure)."

It would not be so necessary to insist on the need for a control group when studying the effects of psychotherapy, were it not for the fact that practically all the studies in the field have neglected to provide such a group. The one or two exceptions to this will be discussed below, but by and large it is depressing to report that this absolutely essential minimum requirement has not been met by ninety-nine out of a hundred studies in this field. It would probably be an idle exercise of ingenuity to try and describe the various possible ways in which control groups could and ought to be used; it is doubtful in any case whether much could be added to the very complete discussion given by Campbell (1957). It may be more useful to consider one or two of the reasons why control groups are so noticeably lacking in this field.

The reason most frequently given is that the effects of psychotherapy are so clear-cut and obvious that no reasonable person could doubt its effectiveness. In answer we may perhaps quote Meehl (1955)—

The history of the healing arts furnishes ample grounds for skepticism as to our nonsystematic "clinical" observations. Most of my older relatives had all their teeth extracted because it was "known" in the 1920s that the clearing up of occult focal infections improved arthritis and other disorders. No doubt the physicians who treated our ancestors by venesection had "observed" many "cures" in longitudinal study of their patients. Like all therapists, I personally experience an utter inability not to believe I effect results in individual cases: but as a psychologist I know it is foolish to take this conviction at face value. In order to bring about the needed research, it will probably be necessary for therapists and administrators to get really clear on this point. Our daily therapeutic experiences, which (on good days!) make it hard for us to take Eysenck seriously, can be explained within a crude statistical model of the patient-therapist population that assigns very little specific "power" to therapeutic intervention. If the majority of neurotics are in "unstable equilibrium" and hence tend to improve under moderately favorable régimes, those who are in therapy while improving will be talking about their current actions and feelings in the sessions. Client and therapist will naturally attribute changes to the therapy. Furthermore, neurosis often shows cyclical fluctuations, and upswing terminators will be perceived as "successful," since therapists do not automatically find out when cases relapse or enter therapy with someone else.

Another argument is the ethical one, to the effect that we are not entitled to withhold therapy from patients in need who might benefit from it. There are several answers to this point. In the first place, the benefits are merely putative, and consequently nothing is being withheld which is known to be of

assistance to the patient. The argument assumes that we have already proved what is in fact the point at issue. In the second place it is a universal practice in medicine, whenever a new method of treatment is put forward, that this new method must receive clinical trials, *including a control group not treated by means of the new method*. If this is ethically admissible in the whole of medicine, even when the most serious disorders are involved and where the *a priori* probability of effectiveness in favour of the new cure may be rather high, then it is difficult to see why a different set of ethical ideals should apply in psychiatry where disorders are rather less serious and where, as we shall see, the evidence regarding the efficacy of the treatment proposed tends on the whole to be singularly negative. In the third place it is quite untrue that psychotherapy would have to be withdrawn from certain people in order to provide a control group. Of all those who are said to be able to benefit from psychotherapy only a very small number have in fact received it. In the United States, at least, there is a high correlation between the income of the patient and the choice of therapy; middle-class patients by and large get psychotherapy, working-class patients physical treatment. It would be very easy indeed to get together large groups of patients who would not in the normal way obtain psychotherapy, and to form an experimental and control group from these patients. If this were done the outcome would not be that psychotherapy was withheld from people who might otherwise benefit from it, because of the experiment; rather, the experiment would be instrumental in bringing psychotherapy to people who would not otherwise have received it. The Cambridge-Somerville Youth Study reviewed below illustrates what can be done along these lines.

A fourth argument which is sometimes put forward relates to the great difficulty in diagnosing psychiatric patients, and the difficulty in assessing the severity of illness. This, it is said, makes impossible the appropriate matching of the experimental and control groups, and thus invalidates the experimental design. This argument, which tends to be put forward by the more sophisticated psychotherapists, is clearly erroneous in that it implies that matching is an essential part of the control-group technique. It certainly is a useful adjunct, where it can be carried out with reasonable reliability, but the essential nature of the control group method implies nothing more than the random allocation of subjects to the experimental and the control groups. When this is done the appropriate statistical formulae for the assessing of sampling errors will enable us to judge the significance of any differences due to the action of the experimental variable.

One further point should be mentioned. It is

sometimes believed that if an experimental and a control group are selected on an appropriate system of random allocation or matched allocation, and if the experimental group is provided with psychotherapy while the control group is not, then any superiority of the experimental group over the control group must be due to the effects of psychotherapy. Such a result, it might then be claimed, would establish the validity of the theoretical system lying at the basis of the psychotherapeutic procedure. Nothing could be further from the truth. The experimental and the control group are differentiated in terms of a large number of variables, any one of which might be responsible for any differences that might be observed. Among the procedures to which the usual experimental group would be subjected, but which might not be experienced by the control group, are the following—

1. physical examination and the medical treatment of all sorts of minor illnesses, etc;
2. long period of rest in hospital, clinic or other institution;
3. manipulation of the environment on the part of the doctor, including attempts to change the attitudes of family, employers, etc. (Klumpner, 1955);
4. more regular and better balanced food in hospital compared with previous existence (cf. the paper by Watson and Camney, 1954, on the effects of nutritional replacement on neurotic disorders).

This list could be extended almost *ad infinitum*, and will be seen that either more than one control group would be required in order to control for these different hypothetical causal agents, or the specification

of the hypothetical causal agent in psychotherapy would have to be much more precise than it usually is, so that a single group could be provided which would take care of all the possible causal agents except the one specified by the hypothesis. Thus if we were to test the hypothesis that interpretation of Oedipus material is a necessary part of psychotherapy, then our control group would have to receive an equal number of therapeutic sessions with an experienced therapist who refrained from giving any interpretation of Oedipus material, but in all other ways duplicated the treatment design of the experimental group. Thus, even if the very rough-and-ready studies summarized below had indicated some degree of effectiveness of psychotherapy, the interpretation of this finding would have been completely open. What we would have gained would have been an indication that research into the distinguishing features of psychotherapeutic treatment might be worth while and might, if accompanied by the formulation of more specific hypotheses, lead to greater understanding. On no account could such a result have been interpreted as unequivocal support for the beliefs of psychotherapists.

We have now discussed in sufficient detail the general logic of work in this field; we must next turn to the actual investigations which have been reported. This will be done in three sections, beginning with those investigations which have used a control group, going on to those investigations on adult patients which failed to use a control group, and terminating with investigations of children in which no control group was used. In the final section the findings will be summarized and the conclusions which we believe can be drawn from these studies will be indicated.

STUDIES USING A CONTROL GROUP

The Cambridge-Somerville Youth Study

Pride of place in any discussion of experiments on the effects of psychotherapy must undoubtedly go to the Cambridge-Somerville Youth Study. It is the only experiment known to us which made use of a properly chosen control group, which used large enough numbers of cases to make the results statistically convincing, which carried on both treatment and follow-up over a sufficiently long period to make the results meaningful, which used objective methods of acknowledged social significance to assess the final outcome, and which investigated the process of therapy itself in an unbiased and properly controlled fashion. In all these ways the study can serve as an example by which to judge the deficiencies of the other work to be reviewed in this chapter.

The aim of the programme has been summed up as

follows by Teuber and Powers (1953): "For approximately eight years, from 1937–1945, this large-scale treatment effort was directed at the prevention of delinquency, by guidance, counseling and therapy, in a group of over six hundred underprivileged boys . . . By setting up a control group, and by keeping unusually detailed records, the Study made provision for quantitative measurement of the effects of therapy, and for systematic attempts at an objective description of the therapeutic relationships."

The first step in the programme consisted of the selection of subjects from among underprivileged boys aged between 6 and 10 whose names had been obtained from welfare workers as being "likely to become delinquent." A list of six hundred and fifty boys having been obtained, the boys were individually matched in pairs on variables such as age, intelligence

quotient, school grade, delinquency rating and ethnic and socio-economic background. The decision as to which boy in each pair should be assigned to the treatment group (*T*) and which to the untreated control group (*C*) was made by the toss of a coin. In this way two equal groups of three hundred and twenty-five boys were obtained whose chances of delinquency as far as could be ascertained were very nearly equal.

As soon as a boy had been selected as a member of the treatment group he was assigned to one of the counsellors employed by the Study and treatment was begun. Details of this treatment are given in the book by Powers and Witmer (1951) and little will be said about it here except to mention that both adherents of the psychoanalytic school and followers of Carl Rogers's non-directive approach participated in the treatment programme. "Regardless of the individual counselor's predilection all treatment consisted of individual, face-to-face contacts. These individual relationships between counselors and boys thus served as the independent variable; they represented 'treatment' . . . they were restricted to the treatment group and consistently withheld from the control group."

The follow-up extended from the end of the treatment period in 1945, when treatment had lasted for between two and eight years in individual cases, to 1948 when the outcome was evaluated. Powers (1949) gives an interesting discussion of the results which would have been reported had no control group been present. Speaking of the treatment group he points out that—

1. "There are seventy *T* boys who are now well past the age of 17, whose careers have been closely followed and who, as boys under 12, appeared to the predictors to be more likely than not to develop delinquent careers . . . after these boys had been through the treatment program, not more than one third (twenty-three boys) committed serious repeated delinquent acts, while thirty-one of them proved not to be delinquent at all."

2. "There are one hundred and sixty-three *T* boys who, when under 12, were rated . . . as probable delinquents." Of these only 14.1 per cent committed delinquent acts which led to their admission to a correctional institution. This rate seems a surprisingly low one in view of the fact that the study, it was believed, included practically all the boys in the two cities participating in the study, with a combined population of 213,000, who showed early signs of future delinquency.

3. The counselors, during the middle period of the program were asked on several different occasions to list all *T* boys who were thought to have "sub-

stantially benefited" by their contact with the study. About two-third of the boys were so listed, and about half of these were reported by the counselors as having been "outstanding" in respect of benefit received.

4. Of the boys themselves more than half (62 per cent) stated that the study had been of value to them. Many of them declared that "they help me to keep out of trouble," and this seems to have been a majority view. Powers concludes: "By such evidence at least, we might reasonably conclude that the study had been successful in preventing delinquency. Many illustrative cases could be given to 'prove' the point in the traditional manner. But the evaluation, though of the customary type, is inconclusive."

The picture changes dramatically when the control group is brought into the picture. The total number of court appearances from the beginning of treatment was recorded, and it was found that ninety-six *T* boys and ninety-two *C* boys were involved, the number of offences being two hundred and sixty-four for the *T* group and two hundred and eighteen for the *C* group. A similar picture is given by the number of appearances before the Court Prevention Bureau. Here we find that forty-nine *T* boys and forty-nine *C* boys appeared on one occasion and sixty-five *T* boys and fifty-two *C* boys two or three times. Teuber and Powers comment as follows—

Such an outcome of the delinquency prevention program of the Study appears to be not only negative, but paradoxical. Instead of confirming the expectation that the treatment group would be less delinquent than the matched control group, there is a slight difference in favour of the control group. This apparent advantage of the control group may be offset, however, by other factors which more detailed statistics seem to reveal. There is a slightly greater incidence of serious recidivism . . . in the control group, and a rating of all offences according to "seriousness" likewise shows a slight advantage of the treatment cases over the controls; there is a tendency on the part of the controls to commit a proportionately greater number of the more serious offences. None of these trends, however, are as yet significant. Unless further developments change the picture . . . the direct comparison between *T* and *C* groups fails to show that the major hypothesis can be sustained; treatment did not . . . reduce the incidence of adjudged delinquency in the treatment group.

It is not surprising that the authors, in contrasting this negative outcome of the control investigation with the enthusiastic beliefs of the counselors, conclude that "quantitative indices . . . are better than professions of faith bolstered by the therapist's prestige and the skillful use of the illustrative case."

The reactions of the therapists themselves are of

some interest. In a detailed study of the therapist-boy relationship it was found that a number of therapists completely misinterpreted the attitudes and feelings of the boys towards themselves and that it was precisely these therapists who "considered their counseling relations as a highly effective tool in producing changes in their charges." Altogether the attitude of the therapists themselves appeared worthy of comment—

To some of the counselors, the whole control group idea . . . seemed slightly blasphemous, . . . they insisted that the relationships established had their value in themselves, irrespective of their possible effects on the boys' behavior, and they were not perturbed when seemingly negative results of the delinquency prevention program became known. Other counselors reacted differently; they felt that research was superfluous, since all the necessary rules of conduct in therapy were already known. When they were informed of the outcome of the Study, they reacted in a characteristic fashion: those who were analytically trained and oriented asserted that the results would have been positive, had analytic principles been applied by all staff members, consistently, throughout the course of the treatment period. Conversely, those counselors, who were followers of Carl Rogers' non-directive approach averred that a systematic use of non-directive methods would have produced more definite success.

The reader may feel that, while the study failed in providing any evidence in favour of the hypothesis that treatment of the kind administered prevented delinquency, this treatment may have had many other important and desirable results. This, of course, is not impossible, but we would like to quote one final paragraph from Teuber and Powers: "We submit . . . that the data yield one definite conclusion: that the burden of proof is on anyone who claims specific results for a given form of therapy. It is admittedly difficult to provide for expensive control settings. . . . But the objective evaluation of therapeutic processes is of such importance that similar studies, in many areas of therapy, are indicated."

The Brill-Beebe Study

The data to be considered next come from *A Follow-up Study of War Neuroses* by Brill and Beebe (1955), which is essentially a statistical analysis of data collected during and after the war in connexion with soldiers discharged from the army for neurotic disorders or returned to the army as cured. The book from which the data are taken is a rather monumental account of a very large number of analyses carried out in great detail. Much of what is said in this book is relevant to the interpretation of the data to be quoted, but it would take us too far afield to go into any detail. Let it merely be said that the combination of background experience characterizing the two

authors—one of whom is a well-known psychiatrist, the other an eminent statistician—gives the book and its conclusions a unique authority and an enviable absence of the all too frequent faults of analysis usually encountered in this field.

The data relevant to this chapter come from two sources. The first relates to the improvement experienced after separation from the service by men suffering with mild or moderate neuroses at the time of separation from the service. Some of the men experienced a breakdown in combat, others outside the combat zone and before reaching it (Z/I zone). These two groups were in turn subdivided into those who received treatment after their separation from the army and those who did not. The results of the analysis are shown in Table XVIII.1. It will be seen

TABLE XVIII.1

PERCENTAGE OF MEN WITH MILD OR MODERATE NEUROSES AT SEPARATION WHO IMPROVED AFTER SEPARATION FROM SERVICE, BY LOCATION AT BREAKDOWN, AND BY TREATMENT SINCE SEPARATION

(Quoted by permission of Brill and Beebe (1955) and the V.A.)

Treatment since separation	Early Z/I breakdown		Breakdown in combat	
	Number of men	Percentage improved	Number of men	Percentage improved
None . . .	82	65	58	62
Some . . .	44	57	42	55
Total . . .	126	62	100	59

that, if anything, those who received treatment improved less than those who received no treatment. The authors summarize their findings in the following words: "Given an individual who broke down in service and who was still ill with a neurosis on discharge, any change in his condition after discharge seems to be related more to sociologic factors than anything else. What his military experience was, *what treatment he had*, and how sick he had been, seemed to make no difference. It is the poorly educated, unskilled individual of limited intelligence who was not well-adjusted before entering the service, and who was more liable to have had marital difficulty after discharge, who is least apt to improve and most apt to get worse. The overall tendency for the entire sample was to improve." We need only add that the special care taken in the follow-up study reported in this volume makes criticism of the conclusions rather less admissible than is usually the case with

studies of a purely actuarial nature, and that the authors must be congratulated on the very careful work done by them to render follow-ups psychologically meaningful as well as statistically comparable. This makes the conclusion that there was no difference in remission of neuroses between those who did and those who did not receive psychiatric treatment all the more interesting.

The other type of comparison made in this book is with respect to soldiers treated in service. Table XVIII.2 shows the mean service period in months

TABLE XVIII.2

TYPE OF PSYCHIATRIC TREATMENT AT FIRST BREAKDOWN IN MILITARY SERVICE AND SUBSEQUENT LENGTH OF SERVICE

(Quoted by permission of Brill and Beebe (1955) and the V.A.)

Type of psychiatric treatment	Number of cases ¹	Mean months of service (including time in hospital) following first breakdown
None	165	8.6
Rest and sedation	150	11.0
Individual therapy	265	10.7
Hospital routine	328	8.4
Total	908	9.5

¹ Count of cases is slightly inflated since some men receive more than one form of treatment.

following first breakdown, analysed by type of psychiatric treatment received. "Men who received individual therapy served somewhat longer, on the average, than men who received routine hospital care, or men who received essentially no psychiatric treatment. Men who received only rest and sedation also served longer than these two groups. *The differences, however, are remarkably small.*" A similar conclusion seems appropriate to the results reported in the next Table XVIII.3 showing the

TABLE XVIII.3

TYPE OF PSYCHIATRIC TREATMENT AT FIRST BREAKDOWN IN SERVICE AND RETURN TO DUTY

(Quoted by permission of Brill and Beebe (1955) and the V.A.)

Treatment	Per cent returned to duty
Essentially no treatment	56
Rest and sedation only	68
Individual therapy	62
Hospital routine	48
Total	57

percentage of casualties returned to duty. Here again "rest and sedation only" appears slightly superior to individual therapy, with "essentially no treatment" very close behind.

The authors find it necessary to correct the overall figures because they found that "individual therapy was given more often to combat than to non-combat cases, to men with a more adequate preservice personality (who were more apt to be in combat), and to those whose illness seemed most severe." The following summary may illustrate the results of a complex method of making the samples statistically comparable—

Although the present study provides no real basis for assessing the effects of the several forms of treatment, it was considered worth while to undertake a single controlled comparison of the several types of treatment. These treatment groups were established—

A—Not more than rest and sedation.

B—Individual therapy.

C—Hospital routine.

Matching was done on the basis of the following characteristics, so that the confounding of choice of treatment with characteristics of the patient might be minimized—

Major area of precipitating stress.

Preservice personality and impairment.

Severity of breakdown.

The three matched treatment groups (A, B, and C) were then compared as to health at separation and condition at follow-up with essentially negative findings. It therefore appears doubtful that there was any difference in the effectiveness of the three gross types of treatment.

In drawing conclusions from these results it may be advisable to keep in mind the warning given by the authors of the report under review: "An *ex post facto* study of different treatments is naturally hazardous; the experimentalist requires an element of physical randomization in the allocation of treatments before he is usually willing to associate differences in outcome with differential effectiveness of therapies. Here the categories of treatment are quite broad and pay little regard to intensity, but in view of the limited resources available for treatment in the military situation only a rough classification is possible." Provided that these possible sources of error are borne in mind and also that it is remembered that war neuroses may differ in many ways from civilian neuroses, the outcome of the two studies just summarized gives a reasonably clear and consistent answer to the question of the effectiveness of therapy after breakdown within the army, and after separation from the army. No evidence of such effectiveness can be found, and the main results of this comparatively well controlled and competently analysed study in so

far as effectiveness of psychotherapy is concerned, must be considered to be completely negative.

The Barron-Leary Study

In this experiment one hundred and fifty psycho-neurotic patients, all drawn from the same clinic population, were tested with the Minnesota Multiphasic Personality Inventory before and after an interval of time during which some of them received psychotherapy, and some of them did not. (Barron and Leary, 1955). "All one hundred and fifty patients had applied for psychotherapy in the psychiatric clinic in which the study was conducted, and all of them had been accepted for treatment; a group of twenty-three cases, however, had to be placed on a waiting list until the hospital facilities became available, and they waited some six months before beginning treatment. Of those who received psychotherapy immediately, eighty-five received group therapy, and forty-two received individual therapy; they included only those patients treated for a minimum of three months during the period of time covered by the study. The aim of the study (was) to discover what changes, if any, occurred in M.M.P.I. profiles of patients who received psychotherapy, and to compare these changes with whatever changes may be observed in the M.M.P.I. profiles of patients who during the same period of time remained untreated."

The psychotherapists carrying out the treatment included psychiatrists, social workers and psychologists; all therapists had at least three years of post-doctoral or post-graduate training and experience. The general orientation was psychoanalytic. Individual treatment consisted largely of ego-orientated psychotherapy on a once-a-week basis, whereas group therapy laid somewhat greater stress on current interpersonal relations.

The experimental and control groups were found to be quite comparable with one another in diagnosis, prognosis, severity of initial condition, age, sex and education. The interval between the initial state and terminal state was 7-00 months for the non-treatment group, 8-23 months for the individual therapy group and 8-63 months for the group-therapy group. The differences between these means fell short of significance, although it will be noted that the time interval for the non-treatment group was noticeably shorter than that for the other two groups, thus making a positive outcome of the study more likely.

None of the patients were so ill as to require hospitalization, and most were diagnosed as suffering from psychosomatic neuroses, obsessive or schizoid characters, phobias, anxiety neuroses and occasional psychopathic or hysterical disorders.

In the two psychotherapy groups significant decreases occurred in the Depression, Hysteria,

Hypochondriasis and Lie scores of the M.M.P.I., whether individual or group. With group psychotherapy there was a significant decrease in the Paranoia and Psychasthenia scores as well. With both forms of therapy, there was "a significant rise in the Ego-strength scores. Finally, for the individual psychotherapy patients there is also a significant rise in the K scale."

Patients of the control group, i.e. those not receiving any treatment, also had fewer complaints on second testing. "On the neurotic triad (D,Ps,Hy) the average decrease is slightly greater for the controls than for the group therapy patients. There is a significant increase in scores on Es, which would suggest that at the end of the waiting period the patients are somewhat more amenable to psychotherapy than at the beginning of that period."

We see, then, that changes in the treatment and non-treatment groups occur in very much the same fashion and in the same direction. The question arises whether the changes in the treatment group are significantly greater than those in the untreated group. The answer is that none of the differences on the psychiatric scales approach significance although in the twenty-four comparisons made altogether one would have expected one difference at least to have been significant by chance. Such a significant difference is in fact found, but it occurs in connexion with the K scale. This is not a psychiatric scale and the meaning of the difference is obscure; the authors do not attempt to interpret it. They conclude that "for the most part . . . the changes tended to be in the same direction for treatment and non-treatment groups, and of about equal magnitude." In so far as we can regard the M.M.P.I. as a reasonable measure of psychiatric status this study would appear to indicate a complete failure of psychotherapy to produce any effects whatever.

Barron and Leary add a rather curious argument. They question whether the patients on the waiting list should really be thought of as "untreated." "In a sense, of course, simply having committed oneself to participating in psychotherapy, and having had a reciprocal commitment from a clinic to afford psychotherapy, even though not immediately, represent a breaking of the neurotic circle. A force for change has already been introduced. In addition, the initial interview and the psychological testing may themselves be therapeutic events." It is, of course, possible that filling in a questionnaire and registering at a hospital may have therapeutic functions. The authors do not really give any reasons for assuming that these events were responsible for the change in the untreated group, and in any case this would not detract from the main conclusion, namely that psychotherapy adds nothing to the total situation.

It should always be possible in studies of this kind to invent *ad hoc* hypotheses to account for the improvement of the untreated group; this does not appear to be a worth-while procedure. What is required, clearly, is a method for *investigating* the factors which are believed to be responsible for the improvement, and which will tell us whether, in fact, these do or do not exert an influence. If the complex and lengthy procedure of psychotherapy cannot be shown to have any effect it does not seem likely to the present writer that filling in a questionnaire, or registering at a hospital, are likely to be so much more powerful in effecting a change.

The Rogers and Dymond Study

This study has been reported in book form under the title *Psychotherapy and Personality Change* (Rogers and Dymond, 1954). Since it is the only one of the studies reviewed here which reports a positive outcome, and since it has been widely quoted and discussed in this connexion, a review of this book obviously cannot be omitted here; the faults of the experimental design are such, however, that on the grounds of merit alone it is doubtful whether it should have been included.

The authors claim that: "This is the first thoroughly objective study of outcomes of psychotherapy in which adequate controls have been utilized. . . . We can, with a reasonable degree of assurance, sort out those changes which occur as concomitants of psychotherapy from those which occur as a result of other factors." The "objective" methods used to assess outcome are counsellor judgements, behaviour ratings by friends, questionnaires and attitude scales, T.A.T. responses and Q-Sorts. These were applied to the subjects of the experiment according to a design illustrated in Fig. 18.1.—

It will be discerned that there is a therapy, or experimental, group and a control group. A portion of the therapy group is set apart as the own-control group in which there is a sixty-day wait period, preceded and followed by the administration of the research tests, before therapy starts. This group is also matched in the so-called "wait group" of the controls. The rationale of the design is that, through the own-control group, we can control for personality factors and motivation for therapy. This is accomplished by comparing changes made during the wait and the therapy periods. The no-therapy control group provides a more precise control for the passage of time and the effects of repeated administration of the tests. If change occurs in the therapy and follow-up period which is greater than the change in the waiting period of the own-control group, or in the equivalent period for the control group, then we would have strong evidence that therapy produces change which is not accounted for on other grounds.

The therapy group consisted of twenty-nine clients whose disorders appeared to have been of a rather mild nature. The own-control group was formed by asking half of these clients to defer their therapy for sixty days. The equivalent control group was made up of twenty-three normal volunteers rather poorly matched for sex, age and social economic status with the patients.

The main criticism to be made of this arrangement is that contrary to the belief of the writers of the book, *no proper control group is in fact provided*. It is

FIG. 18.1. ARRANGEMENT OF EXPERIMENT BY ROGERS AND DYMOND (1954)

(Quoted by permission of Univ. of Chicago Press)

difficult to see what purpose the so-called normal control group serves. No one has, to our knowledge, advanced the hypothesis that a group of normal people not subjected to any kind of psychotherapeutic or other manipulation should change in the direction of greater integration and better mental health. The counter-hypothesis against which controls are necessary in research on the effects of psychotherapy is that spontaneous remission occurs among patients to an extent which equals the alleged effects of therapy; to this counter-hypothesis a normal control group is irrelevant.

When we come to the so-called "own-control" group it must be admitted that the logic of the design is much less susceptible to criticism *provided that the time-intervals of the waiting period and the therapy period are equal*. This is an absolutely essential proviso because the counter-hypothesis specifies that spontaneous remission would be a monotonic function of time; in other words, the longer the period of waiting, the greater the amount of spontaneous remission. If the so-called therapy period is appreciable longer than the waiting period, then we would expect on the spontaneous-remission hypothesis that more such remissions would occur in the therapy period than in the waiting period *irrespective of therapy*, so that it would be impossible to ascribe any difference in outcome between the two periods to therapy. The comparison between the waiting period and the follow-up period with respect to outcome is

only meaningful if the two periods did not differ in any other variable, such as time, which is relevant to outcome. Unfortunately, it is only too obvious from what the authors say that the therapy period was in no way equated with the wait period, but was probably appreciably longer.¹ As the authors themselves admit: "The own-control plan controls motivation for therapy and, indeed, for most of the factors listed above *except passage of time* and environmental influences." The authors do not seem to realize that this admission is sufficient by itself to make the data incapable of throwing any light on the effects of psychotherapy. So far from being able "with a reasonable degree of assurance to sort out those changes which occur as concomitants of psychotherapy from those which occur as a result of other factors," they have designed the experiment in such a manner as to make it quite certain that the theory of therapeutic effectiveness and the main counter-thesis are confounded in the effects to such an extent as to make interpretation of the results impossible.

In principle no more need be said about this study, but nevertheless some of the results are interesting enough to make it desirable to say a few words about the measures used to assess the effects of therapy. Nearly all of these, it will have been noticed, are verbal in nature, calling for Q-Sorts, questionnaire responses, and other types of verbal behaviour. Even if the design of the experiment had been acceptable, verbal behaviour of this type would not be acceptable as the only evidence of improvement. There is ample evidence, from the work of Thorndike (1935), Taffel (1955), Verplanck (1955), Greenspoon (1950), Wickes (1956), Salzinger (1957), and others, that verbal responses can very easily be conditioned to indications of approval or disapproval on the part of the examiner or therapist. It requires no more than a simple nod of the head, or a repetition of the magic syllables "uh-huh" or "hmm, hmm," to produce remarkably extensive and consistent changes in verbal behaviour. It does not follow that these verbal behaviour changes are in any sense accompanied by psychological changes more directly relevant to the process of therapy. Thus we have here another alternative

hypothesis which is disregarded by Rogers and Dymond in their account, although it would again have been better able than their own to account for the actual findings. Some data are in fact provided which strongly support this alternative hypothesis. "It was found that there was no significant difference between the pre-therapy and post-therapy behaviour of our clients, on the average, according to the (ir) friends' observations. . . . When the clients' ratings of their own behaviour were compared with the ratings by their friends, it was discovered that our clients consistently rated themselves less favourably than did their friends; but this discrepancy steadily diminished, so that by the follow-up point their perception agreed much more closely with that of their friends." What appears to happen, therefore, is that there is no observable change in the behaviour of the clients, but that they become conditioned through therapy to make different responses on the purely semantic level to questions regarding their behaviour.

It is not suggested that the data prove this alternative hypothesis. We do not feel that this research was organized or analysed in a manner which makes it possible to draw any definite conclusions and we merely want to draw attention to possibilities which do not appear to have been considered by the authors. Many other such counter-hypotheses could be advanced, and would have to be eliminated before one could even begin to take the results very seriously. What strikes one most about this work is not so much its failure to be conclusive, or even the obvious faults in design and execution; it is rather that the writers appear to pride themselves on the methodological advances of their work over previous studies (among which there are such excellent prototypes of research as the Cambridge-Somerville Youth Study), and that reviewers appear to have regarded this as a major contribution without appearing to realize the crippling defects of design of the study. It would appear almost as if reviewers singled out studies giving positive results with respect to the effects of psychotherapy, while neglecting those with negative outcomes, irrespective of the quality of the work reported.

STUDIES WITHOUT CONTROL GROUPS

Psychotherapy with Adults

The experiments reviewed so far have illustrated the absolute necessity of including a control group in any experiment designed to test the efficacy of psycho-

therapy. When looking at the large body of studies without such control groups we cannot, in the nature of the case, draw any very definite conclusions. What we can do, however, is to try and provide a kind of base-line with which to compare the results of treatment, a base-line which is derived from the best available estimate of remission in the absence of psychotherapy. Our efforts along these lines will, of

¹ An attempt was made to obtain information on this point by writing to one of the authors, but no new information was forthcoming other than that contained on pp. 40 and 44 of the book.

course, suffer from certain obvious defects. The matching of cases is difficult enough when the same investigator selects the treatment and control groups; it becomes almost impossibly complex when all we have to go on is the usually very inadequate account given in a written report. The severity of the illness and the standards of recovery are not usually discussed in sufficient detail to make exact comparisons possible. Data on duration of treatment and the length of follow-up are not usually given in sufficient detail to enable the reader to form an accurate judgement of the time intervals involved. When all these difficulties are added to those usually implied in any actuarial comparison it will be realized that not too much faith should be placed in the results of the comparisons here given, particularly if the results should differ from those of the better-controlled studies reported earlier.

Three attempts are worth mentioning in this connexion as giving us some help in finding the requisite base-line. The first study to be quoted is a rather indirect one by Shepherd and Gruenberg (1957) in which they attempt to estimate the duration of neurotic illnesses not treated by psychotherapy by reference to the general rule stating that *the prevalence of an illness in a population is equal to the product of its incidence and duration*. They quote figures relating to both incidence and prevalence from the Health Insurance Plan of Greater New York (H.I.P.)—

From these data age-specific curves are plotted [in Fig. 18.2] for cases reported as receiving a service in any one year and for cases receiving a service for psychoneurotic illness *for the first time* from H.I.P. in 1951, having been H.I.P. enrollees for at least three previous years without having a service for a psychoneurotic illness. While it is recognized that these are not direct estimates of momentary prevalence nor direct measures of the date of onset, they are superior to most of the other data available in that they are from a large population and that both measures derive from the same data. Because the reports stem from many different physicians trained in many different schools and practicing in diverse groups it is not possible to know just what criteria were being used to make and record these diagnoses. They undoubtedly varied widely. However, whether from accident or from consistency, both the "prevalence" curve and the "incidence" curve are similar to those obtained from other sources of data.

It will be noticed in Fig. 18.2 that the incidence and prevalence curves are not only of the same shape, but are very close to one another, running almost parallel—

From this it may be concluded that the variations in prevalence are due, predominantly, to variations in incidence, since apparently the average duration of the neuroses reported in this population does not vary

equally with age . . . since the prevalence curve here is only slightly higher than the incidence curve, it follows that the average duration of these illnesses is of between one and two years.

The authors sum up their study as follows—

While it is well known that neurotic illnesses can occur at any age and exhibit extremely long courses as

FIG. 18.2. AVERAGE ANNUAL PREVALENCE OF PSYCHONEUROSES IN 1948-1951 AND INCIDENCE OF NEW CASES IN 1951, FOR ENROLLEES IN H.I.P.

The prevalence curves reflect the average annual experience over the years 1948-1951 of all H.I.P. enrollees with twelve months of coverage in any one of those calendar years. There was a total of 60,302 person-years of exposure over this period; 2,714 of these person-years were characterized by the existence of one or more services related to mental illness.

The new case curves show the experience in 1951 of 6,643 enrollees who had entered H.I.P. by January 15, 1948, were still in the Plan on December 31, 1951, and had not received service related to psychoneurosis in 1948, 1949, or 1950.

(Quoted by permission of Shepherd and Gruenberg, 1957)

well as very brief courses, the available data are remarkably consistent in suggesting that neurotic illnesses are most characteristic of early adult life, that there is a rising incidence and prevalence during the twenties and thirties, a parallel rising prevalence continuing into the forties, and then a rapid decline in prevalence of recognized neuroses. From these data it is perfectly clear that, in the mass, neuroses must have a limited course even if untreated; in fact, the best available data would suggest an average duration between one and two years.

As a very rough-and-ready estimate of our base-line, therefore, we appear to have a figure suggesting that neurotic disorders will tend to remit spontaneously over a period of two years or so. The calculations

are rather indirect, and we must next turn to two rather more direct studies.

The first of these is an evaluation by Landis (1938) who begins his discussion by pointing out that—

. . . before any sort of measurement can be made, it is necessary to establish a base-line and a common unit of measure. The only unit of measure available is the report made by the physician stating that the patient has recovered, is much improved, is improved or unimproved. This unit is probably as satisfactory as any type of human subjective judgement, partaking of both the good and bad points of such judgements.

For a unit Landis suggests "that of expressing therapeutic results in terms of the number of patients recovered or improved per hundred cases admitted to the hospital." As an alternative, he suggests "the statement of therapeutic outcome for some given group of patients during some stated interval of time."

Landis realized quite clearly that in order to evaluate the effectiveness of any form of therapy, data from a control group of non-treated patients would be required in order to compare the effects of therapy with the spontaneous remission rate. In the absence of anything better, he used the amelioration rate in state mental hospitals for patients diagnosed under the heading of "neuroses." As he points out—

There are several objections to the use of the consolidated amelioration rate . . . of the . . . state hospitals . . . as a base rate for spontaneous recovery. The fact that psychoneurotic cases are not usually committed to state hospitals unless in a very bad condition; the relatively small number of voluntary patients in the group; the fact that such patients do get some degree of psychotherapy especially in the reception hospitals; and the probably quite different economic, educational, and social status of the State Hospital group compared to the patients reported from each of the other hospitals—all argue against the acceptance of [this] figure . . . as a truly satisfactory base line, but in the absence of any better figure this must serve.

Actually the various figures quoted by Landis agree very well. The percentage of neurotic patients discharged annually as recovered or improved from New York state hospitals is seventy (for the years 1925–1934); for the United States as a whole it is sixty-eight (for the years 1926 to 1933). The percentage of neurotics discharged as recovered or improved within one year of admission is sixty-six for the United States (1933) and sixty-eight for New York (1914). The consolidated amelioration rate of New York state hospitals, 1917–1934, is 72 per cent. As this is the figure chosen by Landis, we may accept it in preference to the other very similar ones quoted. By and large, we may thus say that of severe neurotics receiving in the main custodial care, and very little, if any, psychotherapy, over two-thirds recovered or

improved to a considerable extent: "Although this is not, strictly speaking, a basic figure for 'spontaneous' recovery, still any therapeutic method must show an appreciably greater size than this to be seriously considered."

Another estimate of the required base-line is furnished by Denker (1946). Here is a description of his procedure—

Five hundred consecutive disability claims due to psychoneurosis, treated by general practitioners throughout the country, and not by accredited specialists or sanatoria, were reviewed. All types of neurosis were included, and no attempt made to differentiate the neurasthenic, anxiety, compulsive, hysteric, or other states, but the greatest care was taken to eliminate the true psychotic or organic lesions which in the early stages of illness so often simulate neurosis. These cases were taken consecutively from the files of the Equitable Life Assurance Society of the United States, were from all parts of the country, and all had been ill of a neurosis for at least three months before claims were submitted. They, therefore, could be fairly called "severe," since they had been totally disabled for at least a three months' period, and rendered unable to carry on with any "occupation for remuneration or profit" for at least that time.

These patients were regularly seen and treated by their own physicians with sedatives, tonics, suggestion, and reassurance, but in no case was any attempt made at anything but this most superficial type of "psychotherapy" which has always been the stock-in-trade of the general practitioner. Repeated statements, every three months or so by their physicians, as well as independent investigations by the insurance company, confirmed the fact that these people actually were not engaged in productive work during the period of their illness. During their disablement, these cases received disability benefits. . . . It is appreciated that this fact of disability income may have actually prolonged the total period of disability and acted as a barrier to incentive for recovery. One would, therefore, not expect the therapeutic results in such a group of cases to be as favourable as in other groups where the economic factor might act as an important spur in helping the sick patient adjust to his neurotic conflict and illness.

The cases were all followed up for at least a five-year period, and often as long as ten years after the period of disability had begun. The criteria of "recovery" used by Denker were as follows: (a) return to work, and ability to carry on well in economic adjustments for at least a five-year period; (b) complaint of no further or only very slight difficulties; (c) making of successful social adjustments. Using these criteria, which are very similar to those usually used by psychiatrists, Denker found that 45 per cent of the patients recovered after one year, another 27 per cent after two years, making 72 per cent in all. Another 10 per cent, 5 per cent, and 4 per cent

recovered during the third, fourth, and fifth years, respectively, making a total of 90 per cent recoveries after five years.

The recovery of the patients in Denker's sample as a function of time is plotted in Fig. 18.3. An exponential curve has been fitted to these data. The formula for this curve is—

$$X = 100 (1 - 10^{-0.00435N})$$

where X stands for the amount of improvement achieved in per cent and N for the number of weeks elapsed. While the exact values in this formula should not be taken too seriously, its general form is of course that of the typical learning curve with which psychologists are familiar. It will be seen later that many other data are in good agreement with the generalization embodied in this formula.

The Landis and Denker studies supplement each other in a variety of ways. The patients Landis is discussing were largely working-class; those reported on by Denker almost entirely middle-class. The criterion of recovery in the Landis study was probably more lenient, that of the Denker study less lenient than the criteria usually applied by psychotherapists to their own cases. In spite of these differences the recovery figures for the two samples are not too dissimilar. If we take a period of about two years for each base-line estimate, which appears to be a reasonable figure in view of the fact that psychotherapy does not usually last very much longer than two years and may sometimes last less, we may conclude with some confidence that about two-thirds of severe neurotics show recovery or considerable improvement, without the benefit of systematic psychotherapy, after a lapse of two years from the time that their disorder is notified, or they are hospitalized. These figures are less optimistic than those given by Shepherd and Gruenberg who seem to suggest 100 per cent remission after two years; this is probably because the severity of their cases appears to have been rather less than that of those studied by Landis and Denker. When we bear in mind the different methods used by these two investigators and the very divergent samples studied, we cannot but conclude that the estimates of the rate of spontaneous remission are sufficiently similar to enable us to form a very rough-and-ready guess as to the facts of the case.¹

We must now turn to the effects of psychothera-

peutic treatment. The results of nineteen studies reported in the literature, covering over seven thousand cases, and dealing with both psychoanalytic and eclectic types of treatment, are quoted in detail in Table XVIII.4. An attempt has been made to report results under the four headings: (a) cured, or

FIG. 18.3. IMPROVEMENT SHOWN BY FIVE HUNDRED SEVERE NEUROTICS, NOT RECEIVING PSYCHOTHERAPY, AFTER BETWEEN ONE AND FIVE YEARS

In the formula X denotes the proportional improvement while N denotes the number of weeks elapsing from the beginning of the experiment.

much improved; (b) improved; (c) slightly improved; (d) not improved, died, discontinued treatment, etc. It was usually easy to reduce additional categories given by some writers to these basic four; some writers give only two or three categories, and in those cases it was, of course, impossible to subdivide further, and the figures for combined categories are given. A slight degree of subjectivity inevitably enters into this procedure, but it is doubtful if it has caused much distortion. A somewhat greater degree of subjectivity is probably implied in the writer's judgement as to which disorders and diagnoses should be considered to fall under the heading of "neuroses." Schizophrenic, manic-depressive, and paranoid states have been excluded; organ neuroses, psychopathic states, and character disturbances have been included. The number of cases where there was genuine doubt is probably too small to make much change in the final figures, regardless of how they are allocated.

¹ It may be of interest in this connexion to recall some historical comments by Bockover (1956), who points out that "early American mental hospitals recognized the importance of psychologic and social influences in what was called 'moral treatment' of the mentally ill." He points out that Worcester State Hospital showed a recovery and improvement rate of 60 per cent between 1833 and 1846, and Bloomingdale Hospital one of 65 per cent between 1821 and 1844. For the Worcester State Hospital it is claimed that between 1833 and 1946, 50 per cent of patients had no relapse.

Further details regarding the method of arriving at these various figures are given by Eysenck (1952). The overall figures show that patients treated by means of psychoanalysis improved to the extent of 44 per cent; patients treated eclectically improved to the extent of 64 per cent. These figures may be compared with our base-line estimate of spontaneous remission of 72 per cent. There thus appears to be an inverse correlation between recovery and psychotherapy; the more psychotherapy, the smaller the recovery rate. The difference between eclectic treatment and no psychotherapy is probably too small to be of any significance when we bear in mind the very rough and ready methods used in arriving at these figures. As regards the psychoanalytic results we have classed those who stopped treatment together

with those who have not improved. This appears to be reasonable because a patient who fails to finish his treatment, and has not improved, is surely a therapeutic failure. If we class these cases separately and deal only with the percentage of completed treatments which are successful, we find that a percentage of successful treatments of patients who finished their course must be put at approximately 66 per cent, thus bringing these figures in line with those for eclectic treatment and no psychotherapy at all.

The results have been summarized by the writer as follows (Eysenck 1952)—

In general, certain conclusions are possible from these data. They fail to prove that psychotherapy, Freudian or otherwise, facilitates the recovery of neurotic patients. They show that roughly two-thirds of

a group of neurotic patients will recover or improve to a marked extent within about two years of the onset of their illness, whether they are treated by means of psychotherapy or not. This figure appears to be remarkably stable from one investigation to another, regardless of type of patient treated, standard of recovery employed, or method of therapy used. From the point of view of the neurotic, these figures are encouraging; from the point of view of the psychotherapist, they can hardly be called very favourable to his claims. The figures quoted do not necessarily disprove the possibility of therapeutic effectiveness. There are obvious shortcomings in any actuarial comparison and these shortcomings are particularly serious when there is so little agreement among psychiatrists relating even to the most fundamental concepts and definitions. Definite proof would require a special investigation, carefully planned and methodologically more adequate than these *ad hoc* comparisons.

Psychotherapy with Children

Our review here will follow very closely that published by Levitt (1957), who has summarized a large number of published and unpublished studies and arranged them in tables patterned on that published by the writer in connexion with adults. Levitt also used as the "unit of measurement" the evaluation of the degree of improvement of the patient by the clinicians concerned: "Individuals listed as 'much improved, improved, partially improved, successful, partially successful, adjusted, partially adjusted, satisfactory,' etc., will be grouped under the general heading of improved. The unimproved cases were found in groupings like 'slightly improved, unimproved, unadjusted, failure, worse,' etc."

For various good reasons Levitt refused to use the discharge rate of children's wards in state hospitals as a base-line for evaluating the effects of psychotherapy. Instead he made use of a rather different group of children—

A common phenomenon of the child guidance clinic is the patient who is accepted for treatment, but who voluntarily breaks off the clinic relationship without ever being treated. In institutions where the service load is heavy and the waiting period between acceptance and onset of treatment may range up to six months, this group of patients is often quite large. Theoretically, they have the characteristics of an adequate control group. So far as is known, they are similar to treated groups in every respect except for the factor of treatment itself. Nevertheless, the use of this type of group as a control is not common in follow-up evaluations of the efficacy of treatment. Three studies report follow-up data on such groups. Of these, the data of Morris and Soroker (1953) are not suitable for the purposes of this paper. Of their seventy-two cases, at least eleven had treatment elsewhere between the last formal contact with the clinic and the point of evaluation, while an

indeterminate number had problems too minor to warrant clinic treatment. The samples in the remaining two studies appear satisfactory as sources of base-line data. Witmer and Keller (1942) appraised their group eight to thirteen years after clinic treatment, and reported that 78 per cent were improved. In the Lehrman study (1949), a one-year follow-up interval found 70 per cent improved. The overall rate of improvement for one hundred and sixty cases in both reports is 72.5 per cent. This figure will be used as the baseline for evaluating the results of treatment of children.

It is, as will be noted, identical with that used by the writer with adults.

As regards the results of psychotherapy, Levitt, like Eysenck, rejects a number of studies for various reasons, such as peculiar or inadequate presentation of data, or because results for children and adults were inseparable. The remaining studies cover an age range from pre-school to 21 years at the time of the original clinic contact. However, very few patients were over 18 years at that time, and not many were over 17. At a rough estimate Levitt states that the median age would be about 10 years.

The data are presented in the form of two tables, the first stating the results at the close of psychotherapy. This table which is given on page 714 as Table XVIII.5 shows that the average percentage of improvement, i.e. the combined percentages in the much improved and partially improved categories is 67.05 at close. "As in the case of Eysenck's data, there is a considerable amount of consistency, considering the interstudy differences in methodology, definition, etc."

Table XVIII.6 gives the results of follow-up evaluations, and in this table the follow-up interval is given as a range of years. The average percentage of improvement in the follow-up studies is given as 78.22 per cent. Two further studies are quoted by Levitt as combining Close and Follow-up evaluation and are given in Table XVIII.7. The percentage of improvement for these studies is 73.98, roughly intermediate between the averages of the other two tables. Levitt points out that "the discrepancy between results at close and at follow-up suggests that time is a factor in improvement," and he quotes Denker's study in support of the generalization that "the rate of improvement as a function of time . . . is negatively accelerating." He then goes on to present a rank-order correlation between estimated median follow-up interval and percentage of improvement in the seventeen studies in Table XVIII.6, which turns out to be 0.48 and is statistically significant. Plotting the amount of improvement against time shows that "the curve is more or less the same as that of Denker's data, negatively accelerating with most of the improvement accomplished by 2½ years. . . . This analysis

¹ Estimated average follow-up interval per case.

suggests that improvement is in part a function of time, but the mechanisms involved remain purely speculative. Future comparisons of the results of psychotherapy should properly take this factor into consideration."

Levitt discusses certain features of his data at some length and finally comes to the conclusion that "the therapeutic eclecticism, the number of subjects, the results, and the conclusions of this paper are markedly similar to that of Eysenck's study. Two-thirds of the patients examined at close and about three-quarters seen in follow-up have improved. Approximately the same percentages of improvement are found for comparable groups of untreated children. . . . It now appears that Eysenck's conclusion concerning the data for adult psychotherapy is applicable to children as well; the results do not support the hypothesis that recovery from neurotic disorder is facilitated by psychotherapy."

In evaluation of Levitt's study it should perhaps be said that his control groups are less well chosen than might ideally be desired. Patients who voluntarily break off the clinic relationship while still on the waiting list are perhaps likely to be suffering from less severe and disabling disorders than those who persevere. If that were so then we would expect this group to have a higher spontaneous rating of remission than those who remain. As Levitt points out, it is not known that there are in fact any such differences between the groups, but the possibility cannot be disregarded and ought certainly to be investigated. The fact that although there have been over sixty years of psychotherapeutic work with children Levitt failed to discover in the literature a single properly controlled study, or a single investigation providing unambiguous evidence regarding a base-line figure for untreated groups, is perhaps the most eloquent testimony for the failure of clinical psychologists and psychiatrists to take seriously their task of appraising the effects of the methods they use.

The Wolpe Study

As Winder (1957) has pointed out—

In psychotherapy, it is assumed that the therapist adopts a set of ground rules which guide his behavior. Although the limiting case is probably never achieved, the ideal therapist's contribution would be completely deliberate. This is not to say that therapy cannot be effective if done intuitively, nor that the therapist can be a disinterested administrator of doses of this and that. It is to say that the ideal therapist would provide whatever is essential to therapy (warmth, empathic emotion arousal, intellectual understanding, nonjudgmental understanding, rewards, and punishments, etc.) on the basis of reason and knowledge. The next step is obviously the investigation of the effects of defined techniques, when used with particular kinds of patients, within particular contexts.

This view is also shared by Shoben, when he writes—

No matter how eclectic the counselor's manner of approach to a diagnostic judgement, it seems inevitable that he make use of some theory. Indeed, "clinical intuition" seems to represent in part this kind of utilization of theory when it has been sufficiently well practiced to occur with great rapidity. Certainly, one rarely encounters "intuitive" behavior of this kind in counselors without considerable training and experience. If this point holds in any significant degree, and if one recalls the finding of Holtzmann and Sells (1954) that that clinicians were consistently wrong in their predictions, but that they agreed remarkably well among themselves in their errors, then one can hardly escape the suspicion that something must be amiss in available theories typically employed by clinicians. Even though the situation may have been one where actuarial methods were more appropriate, the agreement in errors hints at some common stereotypes among counselors, rather than at useful theoretical constructs.

As regards the usual process of psychotherapy, some doubt has been thrown on the existence of marked differences in practice deriving from differences in theory by Fiedler (1950, 1951, 1953) whose

investigations have emphasized the role of experience as opposed to that of theoretical preconception. Strupp (1955) has come to similar conclusions regarding experience as a predominant determinant. Certainly the differences between "psychoanalysis" and "psychoanalytic orientated psychotherapy" appear to be vanishing. This seems to be tacitly admitted by Alexander (1953) whose contribution is summarized by Meehl (1955) as follows: "He has been making a very convincing case to the effect that the two products are not 'essentially different,' so long as both are (a) mainly uncovering rather than supportive and (b) based on adequate dynamic formulations. It almost looks as though Alexander shares with his more orthodox colleagues the need to keep a monopoly on the prestigious term 'psychoanalyst,' in spite of the steady breakdown, both in theory and practice, of the distinction it once really made." Certainly psychologists working in mental hospitals will have found it more and more difficult to distinguish in actual practice between adherents of different schools and different theories, and to a very real degree, therefore, it might be said that our device of distinguishing between different schools by appropriate subscripts may be a task of supererogation.

There is one outstanding exception to this general rule, and that is the kind of therapy which derives its theoretical justification not from psychoanalysis but from learning theory, and which may suitably be labelled psychotherapy_{LT}. A long discussion of what is implied in this has been given by the writer elsewhere (Eysenck, 1959), and several chapters in this book are concerned with an elaboration of the principles involved. Here we shall only take note of this novel departure in order to introduce the work of Wolpe (1952, 1954, 1958) who is probably the outstanding exponent of this point of view, and who has published figures on the therapeutic successes of his method and compared them with published figures of the success of psychoanalysis in similar cases. Briefly, Wolpe bases his therapy on the following hypothesis: "When fundamental psychotherapeutic effects are obtained in neuroses—no matter by what therapist—these effects are nearly always really a consequence of the occurrence of reciprocal inhibition of neurotic anxiety responses, i.e. the complete or partial suppression of the anxiety responses as a consequence of the simultaneous evocation of other responses physiologically antagonistic to anxiety." In his view, "neurotic behaviour is persistent unadaptive learned behaviour in which anxiety is almost always prominent and which is acquired in anxiety-generating situations. By 'anxiety' is meant the autonomic response pattern or patterns that are characteristically part of the given organism's response to noxious stimulation, and the term is

applied irrespective of the duration of the autonomic responses or of what has led to them. Anxiety response is unadaptive when it is evoked in circumstances in which there is objectively no threat."

This theory differs radically from the psychoanalytic and has given rise to methods of treatment which also differ profoundly from those usually classified under psychotherapy.¹ Wolpe has reported on a total of one hundred and twenty-two patients treated by him, making use in his report of five criteria originally suggested by Knight (1941): "symptomatic improvement, increased productiveness, improved adjustment and pleasure in sex, improved interpersonal relationships, and ability to handle ordinary psychological conflicts and reasonable reality stresses." In addition, the patient's score on Willoughby's questionnaire is compared with his score at the beginning of treatment, and no patient is regarded as greatly benefited unless his score has dropped markedly, preferably to 20 or less.

Wolpe compared the total results of his investigations with reported results from two large psychoanalytic institutions involving almost four hundred cases. He reports that 90 per cent of his patients were either apparently cured or much improved, and only about 60 per cent of those cases treated by psychoanalysis. "If the favourable results of the present series are, to the extent of 60 per cent, regarded as due to the non-specific reciprocal inhibition that would occur in any kind of interview situation, the additional 30 per cent of good results appear to be attributable to the special measures for obtaining reciprocal inhibition described above. Furthermore, the small average number of interviews needed (four-fifths of the patients had thirty interviews or less) suggests that the use of these special measures early in treatment greatly accelerates the improvement of those patients who would have responded to the non-specific factor alone."

It is, of course, impossible to accept either Wolpe's theory or his figures without question. As regards the theory, he appears to be concerned almost exclusively with dysthymic disorders and to disregard hysterics and psychopaths. There may, as the writer has suggested (Eysenck, 1957), be other methods in addition to that of reciprocal inhibition which may lead to extinction of the faulty emotional habits which constitute the neurotic disorder. As regards the published figures it would clearly have been more

¹ Theory and method of treatment hark back to the Watson and Raynor (1920) study of "little Albert" of immortal fame, and the Jones (1924) sequel. Psychotherapy_{LT} might well be renamed "behaviour therapy," because it differs so much in aim, method, and theory from traditional forms of psychotherapy. A detailed account of the principles of behaviour therapy and the many ways in which it differs from psychotherapy of the Freudian kind is given in *Behaviour Therapy and the Neuroses* by Eysenck (1959).

satisfactory if a control group had been included in the experimental design; the difficulties of using published figures as a control have been pointed out earlier in this chapter. This criticism cannot detract from the very great importance of Wolpe's work. By using the standards of recovery advocated and widely used by psychoanalysts, he has obviated the main criticism that might have been brought against him, namely that of using a more lenient criterion than the psychoanalysts. By publishing a number of his cases in considerable detail he has made it possible for the reader to judge whether the type of patient treated by him is comparable to the type of patient who usually has recourse to psychoanalytic treatment. All in all, criticism of the weaknesses of his paper would come badly from those whose theories have never been submitted to a more rigorous and well-designed test. Of all the hundreds of papers and books examined the writer has found this to be the only one to give positive evidence in favour of one specified type of psychotherapy. Obviously a repetition of the work is urgently required, preferably with two or more control groups to duplicate psychoanalytic treatment, eclectic treatment, non-psychiatric medical treatment, non-directive treatment and no treatment at all. The fact that Wolpe's treatment is so firmly anchored in a very definite theoretical framework which governs the therapeutic procedure much more directly than is usually the case, makes a test of his hypothesis very much easier than would be a similar test of the Freudian or Jungian theory. The considerable difference in approach between Wolpe and the majority of psychiatrists suggests that it may be advisable not to discard our subscripts to the term "psychotherapy" yet.

The Lakin Phillips Study

Somewhat analogous to the Wolpe Studies in the adult field is the Phillips (1957) study in the child behaviour field. Like Wolpe, Phillips declines to use methods based on psychoanalytic theories and puts forward his own "interference" theory, based on modern learning theory. Again like Wolpe, he applies this theory to actual clinical cases and compares the outcome and the duration of his treatment with psychoanalytic treatment. It might be thought that his study would deserve to be regarded as coming under our heading of "Studies using a control group"; it is included here because it did not contain an *untreated* control group, and because the psychoanalytically treated sample which constitutes his control was selected by the therapists according to different principles from those covering Phillips's own selection.

The theory involved may best be summed up in the author's own words—

Very briefly considered, interference theory constitutes the viewpoint that behavior—pathological or otherwise—is a result of various *assertions* made by the individual about himself or about his relationship with others. The person chooses now one kind of behavior, now another, depending on what kind of behavior seems likely to bring (from the environment) confirmation of his assertions. Certain behavior possibilities "interfere" with each other; that is, the person cannot do both at the same time. However, since possible behavior is always selected by a person on the basis of its appropriateness to the environment, the whole process with which we are concerned goes on "in the open." Depth views, which regard the mental life of people as having a kind of deep-going reservoir from which diabolical forces spring, are entirely anathema to the present viewpoint. The depth view is essentially untestable—an elementary, too elementaristic view, one that cannot meet the complexity of problems that we contrive in the laboratory, see in the nursery school, or meet daily in a myriad of practical situations.

The results of comparing an assertion-structured therapy with psychoanalytic therapy are given in Table XVIII.8. Before turning to this table, it should be noted that the number of interviews required by Phillips's method was less than half that required by psychoanalytic methods, a difference which was highly significant statistically. Introducing Table XVIII.8, Phillips writes as follows—

Existing follow-up research on psychotherapy deals almost exclusively with the outcomes of treatment among patients who completed (or nearly completed) therapy. Interest here is shown in the *total problem*: that is, in tracing the *efficiency* with which therapy is brought to the patients, and the *effectiveness* it was judged to have by both patient and therapist on a follow-up basis. This manner of proceeding can give us a more complete picture of the observed value of psychotherapy.

In order to do this, three groups are compared here as to their effectiveness and efficiency; a group treated by the depth-oriented, psychoanalytically-derived methods; a group treated by the assertion-structured therapy method (representing the viewpoint of this book); and a hypothetical group illustrating what one might expect under near-optimum conditions in out-patient, parent-child treatment.

As Phillips points out, "the results shown [in Table XVIII.8] suggest strongly that there are real differences in the effectiveness and efficiency of out-patient, parent-child psychotherapy, when assertion-structured therapy and psychoanalytic-derived depth methods are compared." Particularly striking, in looking at the figures for psychoanalytic therapy, is that of all those applying for therapy, only 25 per cent (forty-five out of one hundred and ninety) were actually accepted for therapy; over half of all applications were refused treatment by clinicians! "This seems like an enormously large figure and one

TABLE XVIII.8

Hypothetical group	100	90	5	5	90	90	81
Assertion-structured therapy	59	53	—	6	53	51	86.4
Psychoanalytic depth- oriented therapy	190	45	103	42	45	21 ¹ (patients' rating) 33 ¹ (therapists' rating)	11.05 ¹ (patients' rating) 17.3 ¹ (therapists' rating)

¹ Therapists' ratings were available for all forty-five patients who completed three or more interviews. Only twenty-seven of these forty-five patients returned questionnaires rating their therapy experience; the twenty-one who rated themselves as having improved somewhat supplied the figure used here.

that is not reflected in the subjective writings and appraisals of clinicians when they report on or discuss therapeutic success and failure."

Phillips has here drawn attention to a fact which is obviously important in evaluating the respective successes of different types of therapy, but which is hardly ever mentioned in the literature. Psychoanalysts are usually very selective in accepting cases for treatment, and unless the proportion of cases accepted for treatment out of the total number of the cases applying for treatment is known, it is impossible to compare the results of psychoanalytic treatment with some other treatment (or no treatment at all) where no such selection has taken place. There is a certain amount of knowledge and agreement as to good and bad prognostic signs in neurotic and psychotic disorders, and by a suitable selection of cases for treatment, it should be easy to beat the "no treatment" or "other treatment" groups not using such a process of selection. It is somewhat puzzling to the writer, in view of these considerations, that no superiority of psychoanalytic methods over others has in fact been demonstrated. Many reasons can be adduced for this; thus it might be that the total effect of psychoanalytic treatment is actually negative, thus cancelling out the effects of selection, or it might be that our principles of selection and prognosis are less valid than is commonly thought. However that might be, this is a point which should be borne in mind in all future studies.

If we disregard these considerations and concentrate on the number of patients completing three or more interviews, we find that fifty-one out of fifty-three are benefited by assertion-structure therapy, but only twenty-one out of forty-five are so benefited by psychoanalytic therapy. These figures are significantly different from each other and suggest strongly the superiority of the non-psychoanalytic method.

It is difficult not to agree with Phillips in his summing up—

One may produce certain arguments against interpreting these results as being in any way adverse so far as psychoanalytic depth-derived parent-child, out-patient treatment cases are concerned. One might say that the methods used are not "true psychoanalysis" of children. However, the record of "true" psychoanalysis of children is hardly better, if as good: witness the work of Klein and Anna Freud. The argument for depth-derived practices cannot be bolstered on the basis of probable value latent in unstudied and unreported upon therapeutic results of psychoanalysis of children. The hard reality here is that, first, there are no convincing results of a follow-up nature that can be used to support psychoanalytically derived (or "true" psychoanalysis) treatment of children; and, second, that the results that do exist fail to support any very hopeful view regarding the effectiveness and efficiency of depth-derived, parent-child, out-patient psychotherapy.

The Albert Ellis Study

A third study comparing psychoanalytic and other types of psychotherapy is reported by Ellis (1957).

He himself has used, on his patients, psychoanalytic psychotherapy of the orthodox kind; psychoanalytically oriented psychotherapy; and finally what he calls "rational psychotherapy"—

The main emphasis of the therapist who employs rational techniques is on analysing the client's current problems—especially his negative feelings of anger, depression, anxiety and guilt—and concretely showing him that these emotions arise, not from past events or external situations, but from his present irrational attitudes toward, or illogical fears about, these events and situations. . . . Where, in psychoanalytic techniques, considerable time is spent on showing the patient how he originally *became* neurotic, in rational analysis much more emphasis is placed on how he is *sustaining* his disturbance by *still* believing the nonsense, or illogical ideas, which first led him to feel and act in an aberrated fashion.

Two groups, closely matched as to diagnosis, age, sex and education were formed, each consisting of seventy-eight cases. The first group consisted of individuals treated with rational techniques over an average period of twenty-six sessions; the second group consisted of seventy-eight patients treated with psychoanalytically oriented techniques over an average of thirty-five sessions. In addition, there was a group of sixteen patients treated by orthodox psychoanalysis, and having an average of ninety-three sessions. Ellis himself treated all the patients in these three groups, and rated them soon after each case had been closed, in terms of whether he or she had made (a) little or no progress while being seen; (b) some distinct improvement; or (c) considerable improvement.

Ellis found "that therapeutic results appear to be best for clients treated with rational analysis and

poorest for those treated with orthodox analysis . . . significantly more clients treated with rational analysis showed considerable improvement and significantly fewer showed little or no improvement than clients treated with the other two techniques." The actual proportions of cases showing distinct or considerable improvement were 90 per cent for rational psychotherapy, 63 per cent for psychoanalytically oriented psychotherapy, and 50 per cent for orthodox psychoanalysis. These figures should be seen in the light of the fact that orthodox psychoanalysis was carried on for three times as many sessions as rational psychotherapy. Ellis concludes: "While the obtained data of the study do not offer incontrovertible proof of the superiority of the technique of rational psychotherapy, they strongly indicate that neither orthodox nor liberal psychoanalytic procedures may be the very last word in effective technique."

Without the use of a non-treated control group it is difficult to say whether the patients treated by rational psychotherapy did better than those treated psychoanalytically because rational psychotherapy had a positive effect, or because psychoanalytic therapy had a negative effect. The former appears to be the more likely hypothesis, when taken in conjunction with data previously quoted, although the other hypothesis may not be altogether absurd. Ellis does not attempt to derive his rational psychotherapy from learning theory, but this should not be impossible. There are obvious similarities, as well as differences, in the approaches of Ellis, Phillips, and Wolpe, and it is to be hoped that properly controlled studies will soon be initiated to test the specific hypotheses of these authors, and compare the results of their methods of treatment.

DISCUSSION, SUMMARY AND CONCLUSIONS

In this concluding section we will first of all state very briefly the main conclusions which may be drawn from the researches outlined above, and will then go on to discuss certain theoretical points to which these conclusions are relevant. The qualifications to which the conclusions are subject have been fully stated in the text and will not be repeated. Nor will it be emphasized again that these conclusions are simply a summary of the existing literature and may have to be changed when further more adequate research is reported.

It appears that eight major conclusions can be derived from the literature—

1. When untreated neurotic control groups are compared with experimental groups of neurotic

patients treated by means of psychotherapy, both groups recover to approximately the same extent.

2. When soldiers who have suffered a neurotic breakdown and have not received psychotherapy are compared with soldiers who have received psychotherapy, the chances of the two groups returning to duty are approximately equal.

3. When neurotic soldiers are separated from the Service, their chances of recovery are not affected by their receiving or not receiving psychotherapy.

4. Civilian neurotics who are treated by psychotherapy recover or improve to approximately the same extent as similar neurotics receiving no psychotherapy.

5. Children suffering from emotional disorders and treated by psychotherapy recover or improve

to approximately the same extent as similar children not receiving psychotherapy.

6. Neurotic patients treated by means of psychotherapeutic procedures based on learning theory, improve significantly more quickly than do patients treated by means of psychoanalytic or eclectic psychotherapy, or not treated by psychotherapy at all.

7. Neurotic patients treated by psychoanalytic psychotherapy do not improve more quickly than patients treated by means of eclectic psychotherapy, and may improve less quickly when account is taken of the large proportion of patients breaking off treatment.

8. With the single exception of the psychotherapeutic methods based on learning theory, results of published research with military and civilian neurotics, and with both adults and children, suggest that the therapeutic effects of psychotherapy are small or non-existent, and do not in any demonstrable way add to the non-specific effects of routine medical treatment, or to such events as occur in the patients' everyday experience.

These conclusions go a little beyond those which resulted from the writer's original survey of the literature which was published in 1952. The conclusion then was simply that published research failed to disprove the null-hypothesis with respect to psychotherapeutic effectiveness. The additional studies which have come to hand since, particularly those making use of a control group, have been so uniformly negative in their outcome that a somewhat stronger conclusion appears warranted. Methodologically, of course, it is impossible to prove that any treatment has no effect whatsoever, and no such conclusion is implied. The results do show that whatever effects psychotherapy may have are likely to be extremely small; if they were large as compared with the effects of non-specific treatments and events it seems reasonable to suppose that some effects would have been found in the studies quoted. It is possible, of course, that effects were looked for in the wrong quarter; psychotherapy may affect personality traits and behaviour patterns other than those relevant to psychiatric improvement as ordinarily understood. In the absence of specific hypotheses and experimental research there is no fruitful way of discussing such a possibility. The writer must admit to being somewhat surprised at the uniformly negative results issuing from all this work. In advancing his rather challenging conclusion in the 1952 report the main motive was one of stimulating better and more worth-while research in this important but somewhat neglected field; there was an underlying belief that while

results to date had not disproved the null-hypothesis, improved methods of research would undoubtedly do so. Such a belief does not seem to be tenable any longer in this easy optimistic form, and it rather seems that psychologists and psychiatrists will have to acknowledge the fact that current psychotherapeutic procedures have not lived up to the hopes which greeted their emergence fifty years ago.

Clearly the matter cannot be left there. It will be necessary in the first place to account for the fact that so many therapists and so many patients believe quite firmly in the efficacy of psychotherapy; this is an undoubted fact which appears to be in contradiction to our conclusion and requires explanation. In the second place it will be necessary to examine the consequences of our conclusions, in so far as they are relevant to psychological theories of neurotic disorder and breakdown; quite clearly the failure of a commonly held belief to be supported by the facts must have some repercussion on widely-held theories which have given rise to such beliefs.

To take the first point first we may perhaps take a clue from Meehl (1955). In a quotation already given he pointed out that therapeutic experiences could be explained within a crude statistical model which assigns very little specific power to therapeutic intervention. If the majority of neurotics tend to improve under moderately favourable external circumstances anyway, those who are under therapy while improving will be talking about their current actions and feelings in the sessions, and client and therapist will naturally attribute any changes to the therapy. Meehl goes on like this—

How will such a statistical system be experienced by therapists? Very much as therapy admittedly appears to its candid practitioners. The best cases are types which seem most likely to improve anyhow. Sometimes there are temporal associations between improvement and interview events of the kind considered important, at other times such covariation is disconcertingly lacking. The therapist gradually conceptualizes the client, but there seems to be no clear-cut connection between the client's learning of this conceptualization and outcome . . . The therapist is like a Skinner-box rat on a schedule of intermittent reinforcement, which generates habits notoriously resistive to extinction. A sprinkling of even 5 or 10 per cent of "specific cures," cases whose shift towards recovery would not have occurred without intervention, could combine with the life-cures and the (unimproved) upswing terminators to yield the experiences therapists actually have in their daily work.

With this statement of the model the present writer would wholeheartedly agree, except that he can find no evidence for the "sprinkling of even 5 or 10 per cent specific cures." The fact that improvement is taking place in the whole group of patients all the

time in conformity with the formula given previously will produce sufficient reinforcement for the growth of very strong beliefs in the efficacy of therapy, prayer, shock treatment, confession, or whatever else may in point of time be associated with the improvement which is taking place anyway. The fact that so many different types of treatment of neurotic disorders and so many different theories regarding neurotic disorders have found enthusiastic adherents among both therapists and patients thus finds an adequate explanation in terms of this hypothesis which is fully in conformity with the teaching of modern learning theories.

How about the repercussions which our conclusions have on modern theories of neurotic disorders? The psychoanalytic view, which is probably much the most widely accepted of all, would seem to generate certain very definite conclusions. Among these would be the following: (1) neurotic disorders have complex roots in early childhood experiences; (2) such neuroses are not self-limiting but relatively permanent; (3) they do not become extinguished in the ordinary way but require definite psychotherapy; (4) such psychotherapy requires the uncovering of the roots which lie at the base of the neurotic disorder; (5) only psychoanalysis, as a method based on Freudian theory, can carry this task to successful conclusion.

The facts summarized in this chapter contradict, in a fairly conclusive manner, all these statements.¹ We have found that neurotic disorders tend to be self-limiting, that psychoanalysis is no more successful than any other method, and that in fact all methods of psychotherapy fail to improve on the recovery rate obtained through ordinary life experiences and non-specific treatment. What is even more conclusive, we have found that there is strong evidence to suggest that short methods of treatment based on an alternative hypothesis are significantly more successful in treating neurotic disorders than is psychotherapy of the psychoanalytic type. This alternative method is based on a point of view which regards neurotic disorders as conditioned responses or learnt habits which are non-adaptive, but which are persistent because they are constantly receiving reinforcement. Like all other habits they are subject to extinction according to rules elaborated by modern learning theory and sufficiently well understood to make possible deductions which can be tested experimentally. All the facts summarized in this chapter

fall in line with this alternative hypothesis, and there are none which contradict it. It would appear advisable, therefore, to discard the psychoanalytic model, which both on the theoretical and practical plain fails to be useful in mediating verifiable predictions, and to adopt, provisionally at least, the learning theory model which, to date, appears to be much more promising theoretically and also with regard to application. Much further evidence is available to reinforce this suggestion and will be found in other chapters of this book; all we can say in conclusion is that such work as has been done on the effects of psychotherapy not only fails to contradict, but lends strong support to this general conclusion.

The more fair-minded psychoanalysts do not appear on the whole to oppose this denial of therapeutic usefulness or theoretical and experimental appropriateness of their model and method. Glover (1955) specifically renounces therapeutic clinics, and has the following to say about psychoanalytic research (Glover, 1952, as summarized by Saslow, 1954)—

The possibility that the psychoanalysts, who gave the impetus to the enormous enrichment of psychological understanding of the last decades, will save the general situation is made to seem rather remote by the picture of psychoanalytic research presented by Glover. His address before the International Psycho-Analytical Congress on research methods in psychoanalysis is based on his own long clinical experience and his observations as Director of Research of the London Institute of Psycho-Analysis for sixteen years. He believes there has been an increasing tendency by psychoanalysts not to apply to their data such scientific controls as are available. He described vividly how hearsay evidence becomes attested conclusion (given an analyst with seniority, enthusiasm or plain dogmatism); how a student whose professional career depends on overcoming "resistance" to the satisfaction of his training analyst can hardly be expected to defend his own scientific integrity against his analyst's theories and practice, so that inherent in the training situation is a tendency to perpetuate error; how, no matter how ideal their own analysis, individual analysts tend to show at meetings and elsewhere their own conflicts and "favorite pathological mechanisms"; how these three factors lead to the stereotyped proceedings of the Psycho-Analytical Association; and how peculiarly susceptible to fashion, "canalized no doubt through a hierarchy of transferences and countertransferences" are psychoanalytic groups. He has the impression that present-day psychoanalytic teaching preserves many of the disadvantages of mid-Victorian pedagogy and few of its advantages, and that the deficiencies of such authoritarian spoon-feeding are not remedied, as is often thought, by the candidate's training analysis. He believes it is time these issues were faced, and that a first task of psychoanalysts is to settle down to the arduous task of defining terms, verifying criteria, and developing reliable statistics. His portrayal of the association

¹ It is interesting that Jaspers (1948), perhaps the most sophisticated and knowledgeable of modern psychiatrists, has no doubt in his own mind that, as far as therapeutic success is concerned, psychiatrists and psychoanalysts are decidedly inferior to all sorts of quacks and "headshrinkers." "Es ist selbstverständlich dass den grössten Erfolg nicht Nervenärzte, sonder—in früheren Zeiten—Schamanen, Priester und Sektenstifter, Wundermänner, Beichtväter und Seelenführer gehabt haben." He specifically quotes Ignatius Loyola, Yoga, Lourdes, and "die Gemütskurbewegung in Amerika."

between lack of scientific productivity and the psychoanalytic training procedure is that of a self-reinforcing system with tremendous internal resistance to change.

If this be true, and it is difficult to disagree with Glover on these points, then the task of those desirous of advancing to a truly scientific study of psychotherapy will be made much more difficult than need be by the opposition of practitioners more interested in the preservation of the *status quo* than in new theories, new methods, and scientific advance generally.

CHAPTER 19

Abnormal Animal Behaviour

P. L. BROADHURST

It does not seem necessary to apologize for the inclusion of the present chapter in this book. Most psychologists and many psychiatrists are by now familiar with the debt they owe to animal studies. If psychologists can point to one achievement of their infant science in which they can properly profess some pride, it is the development of modern learning theory, to which the contribution of animal studies does not need stressing. Here we are not primarily concerned with learning theory, but rather with animal studies which have been more influential in psychiatry than psychology. Since the earliest experiments involving experimental neurosis in Pavlov's laboratory before World War I, a body of work on this topic has accumulated, much of which purports to be relevant to human psychopathology. It is proposed to subject this literature to scrutiny in order to assess its worth and its relevance to the human field. In doing so, the status of the concept of experimental neurosis¹ will inevitably be called into question.

The field to be covered is somewhat arbitrarily defined. Abnormalities of behaviour produced in infrahuman animals by psychological or functional means will be included. Disorders of behaviour resulting from the ingestion of drugs, or from physical methods causing tissue damage, for example, cortical insult, and electroconvulsive shock, will be excluded, since they are treated elsewhere in this book. (*See* Chapters 17, by D. S. Trouton and H. J. Eysenck, 15, by R. A. Willett, and 16, by D. Campbell, respectively.) On the other hand, where such methods have been used in attempted therapy of abnormal behaviour,

they will be considered. Discerning readers will find other omissions: thus, audiogenic seizure phenomena—the so-called “neurotic pattern” rediscovered and described by Maier (1939), the advent of which was hailed as an alkahest for the all-too-solid problems in this field—will not be dealt with. A wealth of studies—Finger (1947), and Bevan (1955) review some two hundred papers—compels the conclusion that the convulsive phenomena observed are primarily a response to loud noise of high frequency, facilitated, in many cases, by middle-ear disease. Similarly no treatment will be found of “abnormal fixations” in learning situations. The evidence so far available (Wilcoxon, 1952) suggests that such “frustration instigated” behaviour (Maier, 1949) can be explained in terms of conventional Hullian learning theory, no new principle of the sort Maier (1956) advocates being necessary. Another omission is the neglect of the phenomena classed as “animal hypnosis.” While our understanding of human hypnosis is still obscure, and it retains a flavour of the abnormal, there are no good grounds for regarding the immobility which may in some circumstances be induced in animals as examples of hypnosis. As Weitzenhoffer (1953) notes, the characteristic of hypnosis in humans is heightened suggestibility to verbal commands and statements. Even allowing for the absence of speech in lower animals, nothing remotely comparable has been reported. A fourth omission which may be detected is a lack of emphasis on those animal studies designed to confirm or refute some aspect of psychoanalytic theory. While some are superior to certain of the studies given prominence below, in that they are at least grounded in a theoretical position and so have greater heuristic potential, they are in general peripheral to the topic of this chapter. Usually they are concerned with an animal analogue of a psychoanalytic mechanism held to be operative in human development (Sears, 1943; Hilgard, 1956), and not with abnormal behaviour as such.

¹ The use of the term “experimental neurosis” is frequently avoided by authors who feel that its use, even when parenthetically protected, suggests acceptance of the implied identification of animal and human neuroses. They prefer circumlocutions such as “behaviour disorders”—seemingly innocuous, but in fact question-begging. Since much of this chapter is devoted to an attempt to examine the validity of the identification mentioned in cases where it is accepted, there is no special reason to avoid the term.

The Definition of Abnormal Behaviour in Animals

Fundamental to the topic of this chapter is the problem of the definition of abnormality in animals. One way of proceeding (Karn, 1940, 1940a) is to accept as experimental neurosis what the experimenter in question defines as experimental neurosis. This leads to the inclusion in other reviews of a paper by Carmichael (1938) which has absolutely no bearing on the topic, apparently because of the mention of the words "experimental neurosis." Some of the rats used as subjects in a maze learning study developed a resistance to running a new maze pattern: "In such cases, the animal's general behavior as indicated by head-turning, irregular movement, and the like, seemed typical of the behavior described by those who have set up so-called experimental neuroses in animals" (Carmichael, 1938, p. 162). That is all. If head turning is to be the sole criterion of neurotic behaviour, then centre-court spectators at Wimbledon would be ideal subjects for the investigation of neurosis in humans!

The alternative is to attempt to define criteria of abnormal behaviour applicable to animals, and then to apply them rigorously. This procedure is clearly superior to relying on the judgement of the individual investigator. In the absence of anything comparable to human neurosis or psychosis in animals in their natural or domesticated states, the selection of such criteria and their definition must inevitably be based on human experience. This is not to deny that bizarre behaviour is not seen in domesticated animals (Croft, 1951), but rather to stress the absence of a body of knowledge about such abnormalities, comparable with that available from human psychiatry (but see Melzack, 1952).

Fortunately, outstanding among studies of the problem (e.g. Hamilton, 1927; Foley, 1935; Lubin, 1943; Davis, 1954) Hebb's penetrating analysis (1947) has provided us with a set of criteria against which to evaluate behaviour thought to be indicative of experimental neurosis. For this purpose, he first defines human neurosis in behavioural terms which do not involve the use of the patient's verbal report of his subjective state, thus allowing the use of the definition at the animal level. To do so, he makes use of his concept of "associated signs" of emotion (Hebb, 1946), for the purpose of which a sharp distinction must be made between behaviour arising from a central state or event, and that central state itself—that is, between neurotic behaviour and neurosis, to which the advocate of the point of view represented by this book would add *neuroticism*, the factorial definition of the constitutional predisposition to the central state itself (see Chapter 1, by H. J. Eysenck). These latter two are, however, constructs designed to classify and to guide research: and it is the former,

neurotic acts, which are the associated signs of the central state. Hebb makes it plain that he is not seeking to establish what this neurotic condition essentially is; it is merely a stage in the search for criteria "to test whether a given disturbance of animal behaviour should be called neurotic."

His analysis of human neurosis along these lines leads him to advance the following definition: "Neurosis is in practice an undesirable emotional condition which is generalized and persistent; it occurs in a minority of the population and has no origin in a gross neural lesion" (Hebb, 1947, p. 11). This definition contains six elements which Hebb considers essential. Omit any one of them and the definition becomes too wide, thus—

undesirable implies evaluationally abnormal—otherwise, e.g. exceptional love of sports is neurotic,
emotional implies involving emotional activity—otherwise, e.g. laziness is neurotic,

generalized implies shown in many ways, not solely in response to a specific excitant—otherwise, e.g. dislike of cats is neurotic,

persistent implies chronic to some degree, especially persisting after the cessation of the specific excitant—otherwise, e.g. transient irritability or depression is neurotic,

occurs in a minority of the population implies statistically abnormal—otherwise, e.g. emotional prudery is neurotic, and

no origin in a gross neural lesion implies the absence of such physical causation as cortical insult—otherwise, e.g. emotional changes caused by brain damage are neurotic.

Hebb notes that though the first four of these criteria are inescapable, they are of different kinds. The fifth, statistical abnormality, he regards as in a sense accidental, being in fact dependent upon the current *mores*. If emotional prudery, for example, were shown to have the same origin as other aspects of neurosis, then neurosis might be said to occur in a majority of the population. The sixth criterion (absence of physical causation) resembles the previous one in being of doubtful theoretical value in the definition, but must be included because of the part both have played in clinical diagnosis of neurotic disorders.

Hebb rejects as components for inclusion in his definition—

neurosis has no known physiological base—because, in his view, an aetiology dependent upon metabolic derangement does not change a diagnosis of neurosis *per se*;

neurosis produces a marked change of behaviour from an earlier base-line—because this concept,

despite its profound influence on research, is not a necessary condition of neurosis; neither is *neurosis follows from some "traumatic" experience like conflict or frustration*—because, though human neurosis can follow psychological strain it can also result from metabolic processes free from strain.

These three principles, Hebb feels, are not essentially true of human neurosis, though they have dominated much theorizing on the topic and have come to be accepted widely as intrinsically related to the neurotic central state. They will, nevertheless, be borne in mind so that the reader who disagrees with Hebb's estimate of their minor function will not feel cheated on that score. Another reason for the retention of these ancillary criteria is that the last two, at least, have occasionally so dominated animal research that positive evidence that the subjects' behaviour has changed after a putatively traumatic experience, has, *ipso facto*, been taken as evidence of experimental neurosis. Examples of this may be noted later.

Enough has been said to indicate that Hebb's analysis provides us with a powerful instrument for evaluating abnormal animal behaviour, especially with respect to its relevance to human studies. It is clearly of little use to argue about human abnormality on the basis of animal findings if such data are themselves not related to abnormality in the animal subjects used. True, the criteria which Hebb offers and of which extensive use will be made, are themselves derived from the human field. But no other course is at present available, and a reasonable anthropomorphism must operate in both directions, that is, not only in employing animal data to illuminate human behaviour,¹ but also in using criteria derived from our more extensive study of human behaviour to evaluate the animal data. In this way, it becomes possible to assess the suitability of such data for the constructions put upon them.

Early Russian Work on Experimental Neurosis

Priorities in science are rarely awarded accurately, and frequently what is stated to be "the first" later turns out to be "the second" or even "the third." This process appears to have started in connexion with the present topic, for, quite apart from the question of priority within Pavlov's own laboratory,

¹ This procedure implies a judicious anthropomorphism, which is inseparable from the use of animals as subjects for experimentation. It is frequently thought that the benefits deriving from such use—invariable in, for example, selective mating, or experiments with large rewards or punishments—are only achieved at the cost of some clarity in the interpretation of the relevance of the findings to human psychology. But both Hull (1937) and Hebb (1947) have examined this problem, and conclude that cross-species identification of behaviour may properly be made if it can be shown that the principles or mechanisms governing the behaviour are the same. (See also Hebb and Thompson, 1954.)

discussed below, we find that the claims of Itard to be the first to have produced an experimental neurosis are advanced (Landis and Bolles, 1949). He used colour and form matching tasks in training Victor, the wild boy of Aveyron, but had to give up when the required discriminations were made so difficult that Victor failed to respond and showed violent anger instead.

But, as is generally known, the idea of experimental neurosis originated with Pavlov. Most accounts give the name of Shenger-Krestovnikova (1921) as the first to observe an experimental neurosis. Her experiment, begun in 1914, is one of the classics of experimental psychology. A dog, conditioned to salivate to the appearance of a circle, but not to an ellipse, was trained to make finer and finer discriminations as the ellipse was made more and more circular. The disturbed behaviour which eventuated when the animal was no longer able to make the required discrimination Pavlov (1927) named experimental neurosis. But Sen (1953) points out that such behaviour had been observed previously in Pavlov's laboratory by Yerofeeva (1912, 1916, 1953), as is clear from the accounts of this early work by Pavlov himself (1927) and by his pupil, Gantt (1944). Yerofeeva's own account, though only published in abstract (1916) is therefore the pioneer report¹ of behavioural disturbances due to conditioning techniques, though, as Pavlov puts it: "The investigation of the higher nervous activity under difficult conditions, carried out in the course of M. N. Yerofeeva's experiments, unexpectedly resulted in the development for the first time of a chronic pathological state which, however, did not attract proper attention" (1927, p. 290). One might add parenthetically that the reason may have been that Pavlov's theory construction was not sufficiently advanced at that time to handle Yerofeeva's facts. On the other hand we must respect his statement that: "Possibly on account of the special nature of the stimulus used in these experiments, all these facts did not attract sufficient attention on our part" (Pavlov, 1927, p. 290).

The stimulus in question was electric shock used as a conditioned stimulus for a salivary response to meat powder, and the facts were these: the original

¹ Available in the West, that is. For the study of much of this early Russian work on experimental neurosis, and on conditioning in general, we must rely on secondary sources and reviews—an unsatisfactory substitute for perusal of original research reports. This difficulty, which is not entirely a matter of a language barrier, has decreased recently with the publication of the English translation of Ivanov-Smolensky's important review (1954), of Liberson's review (1957), and of some further snippets of Pavlov's writings in the edition edited by Koshtoyants (1955). The writer, however, is sufficiently well aware of the difficulties preventing an adequate review of the interesting work going on in this field—see, for example, Zverev (1957) and Fonberg (1958)—to know that this chapter will certainly not do justice to it. He therefore apologizes for this omission and cautions the reader to bear it in mind.

unconditioned defence reaction to this shock, which Yerofeeva characterized as "strong," was abolished by training so that the shock became recognized by the subject as the signal for food, and gave rise to salivation, but when she attempted to generalize the response to other parts of the body than that originally stimulated by the shock, the defence reaction was restored, whatever area was now stimulated. The finding was confirmed on two dogs: the stimulation of new areas with the conditioned shock gives rise to general excitement "qui rend impossible tout travail de canalisation, et détruit tout le travail déjà fait" (Yerofeeva, 1916, p. 240). Note here this early hint of the Pavlovian emphasis on the abolition of previously elaborated simple conditioned responses as a criterion of the abnormal. The original state was only restored in one dog after a period of three months, and not at all in the other (Pavlov, 1927).

And there the matter was left until the well-known experiment of Shenger-Krestovnikova. What appears to have impressed Pavlov is that disordered behaviour similar to that found by Yerofeeva using electric shock was also found in an experiment employing more usual procedures. The programme of work then initiated which absorbed Pavlov's last fifteen years of life has been reported by him (1927, 1928, 1941) and by Ivanov-Smolensky (1954) on whose fuller account the following discussion is based.

The four phases in the study of experimental neurosis in Pavlov's laboratory comprise, firstly, the phase from 1922-5, in which methods used and forms of breakdown were studied and the reaction shown to depend on the dog's nervous "type"; secondly, the next phase in which the concept of overstrain of excitatory and inhibitory processes was developed, the theory of types revised, and phasic states described; thirdly, the last phase before Pavlov's death (in 1936) saw emphasis on changes in complicated patterns of conditioned responses and their inter-relationships; and, fourthly, since Pavlov's death, attention seems to have been concentrated more on the effect of experimental neurosis on other aspects of functioning—reaction to disease, or internal vegetative action—rather than on the neurotic behaviour itself.

After Shenger-Krestovnikova's experiment, the experimental work on neurosis was next taken up by Pavlov's distinguished colleague Petrova (1924, 1926), yet even her experiment appears to be only accidentally concerned with the topic. She was investigating sleep in two dogs chosen as extreme exemplars ("as judged by their general behaviour") of nervous systems based on the dominance of excitation, or of inhibition. To delay sleep on the stand, five diverse sensory conditioned stimuli were used, and delays of up to five minutes between signal and reward were achieved with the inhibitable dog. But with only two

minutes delay the excitable dog showed "general excitation," and with three "became quite crazy, unceasingly and violently moving all parts of its body, howling, barking and squealing intolerably" (Pavlov, 1927, p. 294). Practice with only one stimulus at a time restored normal responses, and delays up to three minutes were achieved: "The differences in the nervous systems of the two dogs was thus made clear," and the main object of the experiment altered to inducing abnormal behaviour by a disturbance in the "normal relations between the two antagonistic nervous processes." The technique of differentiation of positive and negative conditioned stimuli as used by Shenger-Krestovnikova, as well as others involving prolonged inhibition of the two dogs' responses, produced only transient general excitation in the excitable one. Accordingly the painful stimulus used in Yerofeeva's original work—electric shock—was employed. Again the dogs differed in their response to the shock initially but when the strength of shock was increased, delayed reflexes were "disturbed," and conditioned inhibition "incomplete." The consequent abandonment of the use of shock is surprising, if the purpose was in fact to produce disturbed behaviour: nevertheless inhibition continued to weaken so that the excitable dog gave responses to all stimuli, negative as well as positive. The same treatment led to the inhibitable dog developing responses to the shock quite easily, but with practice it led to a decrease in the salivary response to this as well as to all other stimuli. This process was repeated later, when the "ultraparadoxical" phenomenon was observed. This is Pavlov's descriptive term for the condition in which no response is made to positive stimuli, but only to previously negative ones. He clearly always regards this as evidence of abnormal cortical functioning.

Thus: "... in these two dogs with different types of nervous system, prolonged disturbances of the higher nervous activity which developed under precisely identical injurious influences took quite different directions. In the excitable dog the inhibitory function of the cortical elements became extremely weakened. In the quiet dog it was the excitation of the corresponding cells (since the stimuli were identical) which became extremely weak. In other words, two quite different types of neurosis were produced" (Pavlov, 1927, p. 299). Pavlov's ideas about the "type" of nervous system may be conveniently summarized as shown in Table XIX.1.

Ivanov-Smolensky notes that: "For some time after these experiments, the idea prevailed in the Pavlov laboratories that the character of the nervous breakdown as well as of the experimental neurosis evoked by it, depended mainly on the type of the animal's nervous system. However, as we shall see later, experimental facts obtained in the course of

TABLE XIX.1
PAVLOV'S TEMPERAMENTAL TYPES IN DOGS
(Adapted from Babkin, 1938)

"Type" of nervous system	Strength of nervous system		Balance of nervous system		Predominance in nervous system of		Susceptible to nervous breakdown	Type of experimental neurosis seen
	Strong	Weak	Balanced	Unbalanced	Excitation	Inhibition		
Sanguine .	Yes		Yes				No	
Phlegmatic .	Yes		Yes				No	
Choleric .	Yes			Yes	Yes		Yes	Excitatory
Melancholic .		Yes		Yes		Yes	Yes	Inhibitory

further investigations forced us considerably to revise this notion and to introduce substantial corrections" (1954, p. 100). About the same time Rosenthal (1926) precipitated in an inhibitable animal a disturbance of behaviour lasting several months and taking the form of extreme drowsiness. It followed when the inhibitory stimulus of a discrimination involving two tactile rhythms succeeded the excitatory one too closely. Kreps (1924) also produced an inhibitory breakdown by a tactile discrimination, as did Razenkov (1924) in a pioneer experiment on "phasic states" of the cerebral cortex—so called because of the display of phases of more, or less, disordered conditioned responses—by making a single transition from negative to positive conditioned stimulus. This disturbing combination was attenuated by repetition, so that by the fourth presentation no deleterious effect was observed. Siryatsky (1925) also found that discrimination of auditory stimuli occasioned the disappearance of established conditioned responses.

So far, the work in Pavlov's laboratory had been on disturbances produced by difficult discriminations or the temporal contrast of two sorts of stimulation. Rickman's work (1928) was novel because he used unusual or intense stimuli alone: "Experiments were carried out with an animal manifestly belonging to the inhibitory type of nervous system. The following stimuli were simultaneously applied to exert such unusual and intense functional influence upon the nervous system: (1) a loud rhythmic crackle produced by a rattle and resembling the crackle of gun-fire; (2) a sudden emergence in front of the dog of an unusual figure in a mask and fur coat turned inside out; (3) an explosion of powder near the stand; (4) a special swinging platform mounted on the stand and on which the dog was placed." Clearly this dog didn't like fireworks, hated swings, and didn't believe in Santa Claus, because "At the very beginning the animal started, rushed forward, instantaneously rose on its hind legs, set its forelegs against the food receptacle which was before its muzzle and became

rigid, its limbs extended, its head thrown back, its eyes wide open" (Ivanov-Smolensky, 1954, p. 102). A loud tone ended this posture and motor excitement followed for a fortnight, during which no conditioned or even unconditioned responses could be elicited. Re-introduction of the swinging platform caused excitement again: ". . . the neurosis was fully reproduced as if by the mechanism of conditioned reaction to one of the components of the initial pathogenic situation" (Ivanov-Smolensky, 1954, p. 103).

This animal was among those previously subjected to the well-known natural experiment of the Leningrad flood of 1924 so that its pre- and post-flood responses are known. The rescue from the flood exerted an inhibiting influence, judging from the animal's general behaviour (Pavlov, 1927), and this was confirmed by the performance of this particular dog in the conditioning situation. For eight months thereafter whenever the previously learned negative conditioned response was elicited it abolished all other responses. "The powerful and unusual stimuli arising from the flood increased the susceptibility of cortical elements to so great an extent that even a comparatively minute intensification of inhibition from the outside in the form of a conditioned inhibitory stimulus, rendered impossible for a long time any existence of positive conditioned reflexes under ordinary experimental conditions" (Pavlov, 1927, p. 318).

Speransky (1925) also profited by the flood. His dog, of the inhibitable type, appeared normal immediately after the flood, but a week later was restless and refused food. Though increasing the food deprivation had no effect, the presence of the experimenter had, and normal responses were restored after two months. Then, as in Rickman's experiment, a component of the traumatic situation was restored by allowing water to flow under the door of the experimental chamber. Pavlov writes vividly: "The animal jumps up quickly, gazes restlessly at the floor, tries to get off the stand and breathes heavily. The conditioned stimuli serve only to increase the general excitation,

the animal declines the food" (1927, p. 315). Only several months further training restored conditioned responses to their former level. "Thus, the reproduction of a situation somewhat resembling the picture of the flood immediately evoked a new breakdown with the resulting pathological state; this convincingly proved that the first nervous breakdown in the given dog had been really caused by the flood" (Ivanov-Smolensky, 1954, p. 105). In one other dog, called "Brains" because of its facility in forming conditioned responses, Vishnevsky found disturbances of responses four months after the flood, though in this case they had also been seen before the flood (Pavlov, 1928).

Neither Pavlov, nor Frolov (1937), nor Ivanov-Smolensky review the Pavlovian work on experimental neuroses after its first phase in sufficient detail to permit independent evaluation. A further limitation is the current extension of the concept implied by the term experimental neurosis beyond Pavlov's original intention. Experimental neurosis for Pavlov appears to mean a neurosis within the experiment, or even a neurosis of the experiment (cf. Konorski's use of the term "neurotic state of the alimentary centre" (1948, p. 209) to describe the inhibition of eating, frequently met with in classical experimental neurosis); and some writers of Pavlov's school caution against an extension beyond narrow limits. Thus: "Such states were described by Pavlov as *experimental neuroses*; however, it would not be quite correct to regard them as full analogues of human neuroses and stop at that. While some of them actually are what we may call simplified models of human neuroses, others are not" (Ivanov-Smolensky, 1954, pp. 81-82), and: "The designation of these disturbances by the name of 'neurosis' does not mean that they are always of the same type or that they are the same as may be observed in human beings" (Babkin, 1938, p. 616). Nevertheless, Pavlov clearly shows in his writings that he thought them related to human psychopathology.

How then can we evaluate the experiments reviewed above, limited by our dependence upon secondary sources? It is not unreasonable to apply Hebb's criteria for abnormality, bearing in mind that deficiencies revealed may be due to faulty communication. In Table XIX.2, therefore, will be found summarized the main points of these experiments, as they relate to Hebb's criteria. To mitigate the inevitable arbitrariness in such a procedure the "benefit of the doubt" has usually been given to the Russian worker.

It is clear from the Table that a principal failing of this work in its putative relation to the abnormal is the lack of data about responses external to the experiment. Thus it is only by inference that we learn that the criterion of statistical abnormality of the

responses of the dogs rescued from the flood may have been met. We are told that all the dogs were rescued from their kennels; if all had been equally affected we should no doubt have heard of it. Even more striking is the lack of information about the generalization of the abnormal behaviour—little being reported about the subject's behaviour outside the conditioning situation. This neglect throughout of the more purely behavioural aspects of the animals' response follows from Pavlov's conviction that his field of study was physiology and not psychology. For him the conditioned reflex method demonstrated the totality of the subjects' higher nervous activity, hence the paucity of detail about other aspects of behaviour. But Hebb has argued that the concept of human neurosis as a behavioural abnormality implies a response which has generalized beyond the causal stimulus. Without this, demonstrations of animal abnormality become less convincing, as they may, for example, be merely fear responses, and as such within the normal range. The available evidence suggests the verdict on this pioneer Russian work should be the Scottish one of "not proven."

American Work on Experimental Neurosis: Liddell and the Cornell Group

Several reviews of literature on the topic of this chapter already exist; in addition to Hebb's important contribution (1947), those by Babkin (1938), Cook (1939), Karn (1940; 1940*a*), Gantt (1944), Freeman and Watts (1944), Liddell (1947), Russell (1950), Patton (1951), Kupalov (1952), Pilgrim and Patton (1953) and Beach (1953) may be cited. The justification for adding another lies perhaps in the greater rigour of the approach adopted here, as well as in the growing recognition of the limitations of the results achieved by traditional methods (Harlow, 1956; Chance, 1957). Furthermore, the output of work appears to have passed its peak. Three major American contributions to the literature appeared in the early 1940s (Anderson and Parmenter, 1941; Masserman, 1943; Gantt, 1944). This productivity, originating in Liddell's pioneer work on conditioning in sheep (1926) and the establishment in 1929 of the Pavlovian Laboratory at Johns Hopkins University under Gantt, a translator and former student of Pavlov, has not been equalled since. It is proposed, therefore, to organize our discussion of the readily available literature around these three contributions, and pride of place, because of its range, novelty and volume, must go to the Cornell group associated with Liddell.

The story is told (in Tanner and Inhelder, 1956) of how Liddell was studying thyroidectomy in sheep and goats and found no effects on maze learning (1925, 1925*a*; Liddell and Simpson, 1925). He therefore

turned to conditioned reflex methods for a more precise measure (Liddell and Simpson, 1926; Liddell and Bayne, 1927). This quickly led to the incidental and unintentional production of experimental neurosis in a sheep (Liddell and Bayne, 1927a), and the field of study changed. The techniques routinely used resemble the Russian, but differ in that the salivary reflex—difficult, but not impossible (Denton, 1957), with ruminants like sheep—was avoided, and the motor response to an electric shock to the foreleg, which appears as a brisk muscular flexion, used instead. This unconditioned response becomes associated in the usual way with a conditioned stimulus which then evokes it before, or in the absence of, the shock. In a study (Liddell, James and Anderson, 1934) of this motor conditioned response in the sheep, and four other species (dog, goat, pig and rabbit), it is claimed as an advance on Pavlovian procedure, because it is a more discrete event than salivation, and is easily quantified using a work accumulator (*see* Anderson, 1941 and Liddell, 1942, p. 191), though this device has not been consistently used. While physiological measures, such as respiration, heart rate and P.G.R., were recorded as well as movement of parts of the body other than that to be conditioned, only a few subjects of species other than sheep were used, and the normative data presented is inadequate, no statistic more refined than a range being given. From observations of the stressful aspects of the conditioned motor reflex procedure it is concluded that nervous strain develops when negative conditioned stimuli are introduced, restraint thus being required of the animal.

This point is developed in a paper on four cases of experimental neurosis in sheep (Anderson and Liddell, 1935). The first, briefly reported before (Liddell and Bayne, 1927), showed persistent movement of the conditioned forelimb during intervals between the stimuli when they were increased from ten to twenty during a period of six days. Moreover, contrary to its previous willingness to enter the laboratory, it now resisted and had to be forced in and on to the stand. Once there it was calm enough: "As soon, however, as the experimenter left the room the sheep began its fidgeting tentative movements of the left foreleg" (Anderson and Liddell, 1935, p. 334). Neither this sheep's thyroidectomized twin, nor two other non-operates were disturbed by comparable increases in conditioning practice. These comparisons are vitiated, however, by the operation in the first case, and the use of somewhat different conditioning signals in the second. Short periods of rest did not restore the former precision of the sheep's responses, but one and a half years away from the laboratory did. Resuming work with delayed responses precipitated further "interval activity" and resistance to experimentation. In a second sheep, the introduction of non-reinforced con-

ditioned signals to be discriminated from the positive ones caused similar symptoms, still apparent five years later. In a third, good discrimination between different metronome rates was achieved; only when the different rates were presented in the same experimental session did the disturbed behaviour appear, and was present three years later. Rhythmical patterning of a simple discrimination caused similar restless and unmanageable behaviour in a fourth sheep, although it did not affect another similarly treated. Thus each neurosis was of an excitatory nature in Pavlov's sense, though passing through a premonitory inhibitory phase in two cases.

An apparatus devised for measuring heart rate outside the conditioning chamber, as well as inside it, represents a methodological advance by this group (Anderson, Parmenter and Liddell, 1939). By strapping to the sheep the chest-piece of a stethoscope attached to a long, flexible tube at the end of which the hidden experimenter listened, counting the beats,¹ records of heart rate of six sheep were obtained. Two of those whose experimental neurosis is described above are included in a group of four "neurotics," and there were two normals. The authors conclude: "Sheep in which an experimental neurosis has been developed reveal, upon examination, a cardiac disorder which is characterized by a rapid and irregular pulse and by extreme sensitivity of the heart's action to conditioned and other stimulation" (Anderson, Parmenter and Liddell, 1939, p. 100). Evidence for rapidity of pulse comes from a systematic though unspecified number of observations as shown in Table XIX.3, which may or may not indicate a statistically significant elevation of pulse rate. Evidence for irregularity and sensitivity comes from the experience of the observers in comparing the normal and neurotic sheep under different conditions, but since one of the "normals" became "neurotic" later (Anderson and Parmenter, 1941; Rose, Tainton-Pottberg and Anderson, 1938), the value of these comparisons is dubious. Thus recognition of the methodological advance is tempered by the absence of any satisfactory statistical treatment of the data collected. Unfortunately this criticism is also applicable to the major work of this group (Anderson and Parmenter, 1941).² In this monograph the series of

¹ In later work a cardi tachometer and a cardiograph were used.

² These strictures do not apply solely to the work of the Cornell group. Most of the work in this field is characterized by a poverty of experimental design, manifest in inadequate control, and the almost entire absence of quantitative data, appropriately analysed. Perhaps workers have been overinfluenced by Pavlov's manner of exposition as seen in translation. Typically, he makes a statement and then cites a detail of an experiment to support it. But not all investigators follow his manner of working, which involved scrupulously checking experimental findings (Babkin, 1951), and which to some extent renders statistical sophistication unnecessary.

TABLE XIX.3
THE PULSE RATE OF NORMAL AND NEUROTIC SHEEP UNDER NATURAL AND
LABORATORY CONDITIONS

cases of experimental neurosis is extended to ten (seven sheep, and three dogs) some of which had been reported before (Anderson and Liddell, 1935; Anderson, Parmenter and Liddell, 1939; Liddell, Sutherland, Parmenter and Bayne, 1936; Liddell, Sutherland, Parmenter, Curtis and Anderson, 1937; Anderson, 1939). All cases of experimental neurosis except one in a dog with whom a salivary conditioning method was used, resulted from motor conditioned reflex procedures. Three main topics are dealt with: the signs of neurosis, the methods which initiate and maintain it, and therapeutic procedures. Reproduction of polygraph recordings to illustrate the points discussed does not prevent the presentation from remaining anecdotal in flavour.

The signs of experimental neurosis are numerous. *Hyperirritability* showed as increased conditioned motor responses and startle responses. *Restlessness*, especially interval activity, is shown to be greater in a neurotic animal than in a normal, and in one sheep transferred from the reaction foreleg to the other.¹ The diurnal activity of the four sheep—two neurotic and two normal—was measured by means of a large activity platform, or a leg pedometer (Curtis, 1937a).

¹ An identical occurrence in two dogs also undergoing motor conditioning to shock (Drabovitch and Weger, 1937) hardly deserves the appellation of experimental neurosis since the authors explicitly deny any generalization—the dogs otherwise remaining normal.

The authors recognize that the resulting data are insufficient for exact comparison, principally because different breeds of sheep were used. Nevertheless, the figures suggest, not a greater total activity of the neurotics, but a decrease of the normal nocturnal rest: "The neurotic animal, like the neurotic human, is apparently a frequent sufferer from 'insomnia'" (Anderson and Parmenter, 1941, p. 37). *Postural changes* were prominent, especially among cases of inhibitory neuroses—now noted for the first time as occurring among sheep. In the conditioning situation one regularly adopted an unusual posture with concavely flexed back, and another extended the reaction limb instead of flexing it. One dog showed "pseudo-decerebrate rigidity" which allowed passive moulding of limbs into bizarre poses.

The records of *respiration* taken from many sheep suggest that the experimentally neurotic ones, as well as displaying a disordered rhythm, have an increased breathing rate, and a long-range pneumograph technique confirmed that these differences persist in the animals' living quarters. Data from systematic observation of respiration in twelve dogs suggest that the three neurotic animals had a higher breathing rate, but these data are inadequately presented for appropriate comparison. *Cardiac records* are taken as confirming previous findings, and reveal conditioning of cardiac responses. A curious inversion of the T

wave (part of the P.Q.R.S.T. cardiogram complex) was observed in three sheep, but since only one was neurotic, the significance of this observation is not apparent. Another anomaly—the coupled heartbeat—seen in the cardiograph records of one neurotic sheep is probably an artefact to which this method of recording heart rate is prone. Another example, in this case recognized as a double recording of two (instead of one) aspects of the complex, is noted by James (1943). *Elimination* of urine and faeces in the laboratory was only observed among neurotic animals, and their *social behaviour* changed in the direction of greater solitariness, especially noticeable in the normally gregarious sheep. Neurotic animals occasionally attacked the experimenter, normal ones never. Maternal and sexual behaviour is briefly reported, but five of the seven sheep were castrated males. In later accounts of work on sheep, Liddell (1953, 1956) notes this deficiency, and characterizes the conditioning procedure as an essentially “castrating” one for the young ram, which is not tolerated by adult ones, two of whom became aggressive with a defence reaction (butting) to each stimulus (Liddell, 1951).

The conditioning procedures which gave rise to the signs of abnormal behaviour were, in order of importance, discrimination between positive and negative stimuli, experimental extinction of a positive conditioned response, and training according to a rigid time schedule. Liddell claims (1947, 1950, 1951) that this method, employing the positive conditioned stimulus only, is standard procedure for producing experimental neurosis, and even that the type of neurosis may be determined by the interval between the stimuli, five to seven minutes giving an excitatory and two minutes an inhibitory breakdown. Anderson and Parmenter only show that nervous behaviour was *maintained*—though for six years—by this method. Increasing the amount of practice as a method of producing breakdown is not now stressed.

Therapeutic procedures resemble Pavlov's, with emphasis on *rest* from experimentation and the use of *drugs*. “The periods of rest we have given our animals have ranged from one month to as long as three years. The result was somewhat beneficial. However, the improvement was of short duration once testing of the animal was resumed. The degree of improvement did not seem to be a function of the duration of the period of rest” (Anderson and Parmenter, 1941, p. 74). The effect of sedatives (sodium bromide, Sodium Amytal and ethyl alcohol) on the excitatory neurosis of one sheep is unclear from the few data presented. In a somewhat more extensive test, phenobarbital increased the magnitude of the conditioned motor responses, decreased the interval activity, and made the animal quieter in the barn. A similar effect had been found (Liddell, Anderson,

Kotyuka and Hartman, 1935, 1935a) in earlier work on four neurotic sheep in which the hormone, cortin, was used and its effect contrasted with that of adrenalin which decreased the magnitude of the response, and increased interval activity. Thyroxine is said to have no effect. These suggestive findings do not appear to have been followed up (Liddell, 1952a). *Spontaneous remission* of the neurosis in one old sheep aged twelve years may have resulted from senile changes, though in another case disordered behaviour persisted until death some thirteen years after it was first observed.

The admirable longitudinal approach of these authors is seen in the complete case histories of the subjects¹ which are appended to the monograph. The patient documentation of experimental and observational work over long periods—the shortest being two years in the dog, and five in the sheep—is unfortunately marred by the absence of any standard experimental approach. Procedures vary between subjects, and with the same subject from time to time. Considering that the subjects were of different species, and different breeds within species, it is not surprising that no new principles emerge from the plethora of observations. The need for precise standardization of experimentation on a sizeable number of subjects now appears to have been recognized (Liddell, 1950, 1950a). By means of central polygraph recording, “. . . our arrangements for conditioning six to eight sheep or goats simultaneously by automatic controls will enable us to observe and compare enough animals subjected to standard stress situations to arrive at statistically valid conclusions” (Liddell, 1950a, p. 166). Its use with four sheep of, however, varying ages and strains, led to another of the “accidental” experiments which abound in the literature on experimental neurosis. A fault in the electrical circuits caused a slight shock to be delivered to the foreleg with each click of the conditioned metronome signal in advance of the reinforcing unconditioned shock. Only after this was repaired and the “warning” shock no longer received did experimental neurosis quickly supervene in all cases (Liddell, 1950a). But no further behavioural details are given, nor have any other reports of the use of this ingenious procedure of simultaneously conditioning many subjects come to hand.

The Cornell group have also done work on two additional species, and further work on the dog. In these, strict Pavlovian techniques were not always followed. James (1943) used a conditioned avoidance technique (James, 1934); in his work on two dogs, and sought to introduce a conflict into the situation by

¹ The seven sheep reported to have developed experimental neurosis represent a quarter of a total population of twenty-eight tested. For the dogs, the figures are three out of twenty-six.

weighting down the foot which the dog had to withdraw to avoid shock. Thus, one Alsatian was attempting to lift over thirty pounds on its foreleg to avoid a shock of the maximum (unspecified) intensity. It does not seem remarkable that "... total flight and escape behaviour was released, signalled in the kennel by the entrance of the experimenter rather than a specific signal in the laboratory" (1943, p. 117). After six months rest, the first signal caused one dog to react so vigorously that it fell out of the harness (James, 1953). No data on other aspects of the dogs' behaviour are presented (Jensen, 1945).

The early work of this group on the pig is diffusely reported with few experimental details (Liddell, 1936; Liddell, Sutherland, Parmenter and Bayne, 1936; Curtis, 1937; Liddell, Sutherland, Parmenter, Curtis and Anderson, 1937; Liddell, 1938; Sutherland, 1939; Altmann, 1941). Liddell's own account (1942, 1944) relates how early attempts (Liddell, James and Anderson, 1934) to condition adult pigs required brute force to handle them, whereas training pigs when young succeeded. An instrumental conditioned response was used, one pig learning to lift the lid of a food box at the positive conditioned signal, and not to do so at the negative one, which was sometimes reinforced with shock to the foreleg. Only when the pig was punished with shock for opening the box before the positive signal, was abnormal behaviour precipitated. This finally took on an inhibitory nature; the pig delayed responding to the positive food signals—during which time it was unresponsive even to food on its snout (Liddell, 1938)—and finally ignored them altogether. Respiration was slow and deep (Liddell, 1951), and the pig's behaviour outside the conditioning situation "... showed a marked change from friendliness to irascibility, so that it was no longer to be trusted" (Liddell, 1942, p. 393).

Later Marcuse and Moore (1942, 1946; Moore and Marcuse, 1945) did careful work at Cornell on several aspects of conditioning in pigs. In only one case was abnormal behaviour observed (1944), but the authors doubt that this "tantrum behaviour" deserved the name experimental neurosis, since the pig still came to the laboratory willingly, and its heart rate during its vocal protests remained unchanged.

The interesting Cornell work on goats is even more diffusely reported than that on swine. In early work, positive and negative motor responses were conditioned in adult goats (Goldman, 1939), using a rigid time schedule, usually with a two-minute interval, between stimuli. Liddell (1947, 1949, 1950, 1951) notes that a "tonic immobility" was thus produced with rigid extension of the reaction foreleg. There was no cardiac conditioned response, and though respiration was disordered in the conditioning situation, it was normal outside it (Liddell, 1951). The

condition persisted for seven years in one case and eight in another (Liddell, 1952). More recent work has employed the technique for conditioning in freely moving animals (Parmenter, 1940), and has been concerned with the protective effect of the presence of the mother goat against the effects of a rigid time schedule of conditioning in the young kid. The use of flexible suspensions permitted the experimenter to record activity and respiration and to shock the foreleg. At first the method of conditioned avoidance of shock appears to have been used (Liddell, 1951), the experimenter being present in the room with the kid, and turning off the shock if the leg was flexed to the conditioned signal. Later, training was begun with eight young kids, four of whom had their respective mothers with them, while their twin siblings underwent the same conditioning schedule (of ten seconds of darkness followed by shock every two minutes) alone in an adjoining room. The results reported (Liddell, 1950, 1950a, 1952, 1954; Patton, 1951; Tanner and Inhelder, 1956) show that after relatively few trials, compared with the precipitation of experimental neurosis in adult animals, a restriction of movement of the isolated kids occurred. One of the experimental isolates ceased sucking and died. Comparable findings are reported in an experiment involving twin lambs and their mother (Liddell, 1955). Liddell reports (1954) that two years later experimental neurosis was precipitated in the now adult goats from the experimental group merely by restraining them in a conditioning harness for two hours a day for twenty days, and giving signals every six minutes, whereas the adult controls were not so affected. It is to be regretted that all these suggestive findings, which have aroused widespread interest (e.g. Bowlby, 1951), do not appear to have been reported in detail, especially since the method of co-twin control is a powerful tool for the isolation of environmental effects.

How do the Cornell findings stand in relation to Hebb's criteria of abnormality? It is plain that many examples of behaviour reported are abnormal in the sense of being *evaluationally undesirable*, not only from the point of view of the experimenter and of the individual subject, but also from a broader biological standpoint. An example is the reduction in gregariousness in one sheep which, it is claimed (Anderson and Parmenter, 1941), led to its death when the flock was attacked by dogs. The *emotional* quality of many reactions is confirmed by the disordered physiological measures, and there is no evidence that the behaviour reported may be attributed to a *gross neural lesion*. The *persistence* of the disorders is well established. On Hebb's ancillary criteria the Cornell cases stand up well: there is usually *marked change in behaviour* from an earlier base-line, though established solely in terms of conditioned response measures, the behaviour

outside the laboratory being observed casually or not at all. The selection of cases is not always beyond reproach in this respect, e.g. the use of a sheep for a study of experimental neurosis "... because of its atypical reactions outside the laboratory" (Anderson, Parmenter and Liddell, 1939, p. 98). The occurrence of *trauma or conflict* in most cases can be agreed, especially if Liddell's view (1942a) of the conditioning procedure as an essentially traumatizing one is accepted. But some difficulties arise with the important criteria of *statistical abnormality* and *generalization*, despite this group's laudable efforts in this latter direction. Two sorts of generalization may be distinguished in this connexion. Firstly, what might be termed system generalization, the involvement in the disturbed activity of segments of behaviour not specifically manipulated by the experimental procedures. This category is admittedly somewhat artificial, since the whole animal goes into the experimental situation, so all aspects of its behaviour may be modified, but one can point to certain ones unlikely to be thus modified, such as innate responses to stimuli remote from those used experimentally. Nothing in the work of the Cornell group suggests such an effect as, for example, the involvement of the urino-genital system of Gantt's dog "Nick" (see later). The failure of gregariousness noted in some sheep hardly qualifies, since isolation from the flock is itself a component of conditioning.¹ The emergence, or re-emergence rather, of cardiac, respiratory and motor disturbances in the experimental situation is less impressive because they are clearly components of the initial unconditioned reaction to electric shock. The fact that they re-emerged after being suppressed by adaptation to the situation is probably not of significance—change from a previous base-line not being an adequate criterion of neurosis—and on some views is exactly what one might expect, as will be shown later. The second kind of generalization may be termed situational generalization, that is, the temporal spread of disturbed behaviour to situations outside the experimental one. This Liddell has called "the subject carrying its troubles into the barn." Despite the surmounting of the difficulties involved in obtaining quantitative measures of physiological variables in the free situation, the evidence collected on this point fails to convince. The data are fragmentary, inadequately controlled and open to two fundamental objections as Hebb has noted (1947). The apparatus used to measure respiration, heart rate, etc., were themselves components of the laboratory situation, and may themselves have initiated the disturbances they

recorded by serving as conditioned stimuli for them. It may only seem that the sheep has carried its troubles to the barn because the experimenter has followed it there with part of the laboratory. This is a logical objection which can only be met by control data from longitudinal investigations of the measures in question *before* conditioning starts. It is not enough simply to compare neurotics with normals (Anderson, Parmenter and Liddell, 1939). The second objection is that the data on generalization were usually gathered during the period when the subjects were undergoing conditioning training and displaying signs of neurosis in the experimental situation. Regarding the neurotic animals' "insomnia": "Anxiety at night is not evidence of abnormal emotional functioning when the animal is exposed every morning to noxious stimuli" (Hebb, 1947, p. 13).

The evidence on the final criterion of statistical abnormality is even scantier, though it is allowed that it would be a large undertaking to establish the statistical abnormality of a behavioural response using animals larger than the rat. A reasonable quantitative expression of this criterion may be adopted from the human field: Fraser (1947) found that 10 per cent of an industrial population showed clinical signs of neurosis. Now, the evidence presented suggests that in the sheep—the species most studied—about 25 per cent developed experimental neurosis. Though the sample is still too small to allow anything less tentative, this figure seems more suggestive of a normal reaction to the stresses imposed, when the differences in its intensity and the almost certain differences in constitutional predisposition are considered. Thus, one sheep remained unaffected by conditioning procedures far more extensive and strenuous than those causing breakdown in others (Anderson and Parmenter, 1941). To sum up, it appears from the evidence reviewed that the Cornell group's efforts to establish the Pavlovian experimental neurosis on a firmer basis have produced equivocal results, and the reasons for this have been indicated. Liddell, however, believes that in some animals "... subjected to experimental procedures there is satisfactory evidence of a psychopathological state, i.e. a breakdown of the emotional mechanism" (1947, p. 571).

In considering Liddell's theoretical formulation of the causation of the disorders he and his colleagues have studied, it should be noted that he has consistently avoided the cross-species identification implicit in Pavlov's term experimental neurosis, which he regards as unfortunate (1950). Nevertheless, he does contend that the behaviour is abnormal, and further that it has relevance for human psychopathology: "It may be regarded as the analogue or prototype of the elaborately differentiated forms of human abnormality.

¹ The use of a "social sheep" during conditioning, mentioned in the early Cornell work, appears to have been dropped later, though Liddell's later work on maternal deprivation apparently begins systematic exploration of this rather obvious variable.

Like them, however, it may be self-perpetuating and persist until death" (Liddell, 1947, p. 572). What then, in Liddell's view, is the origin of this disorder? It stems from the view he has developed of the conditioning procedure as in itself constituting a stress situation. "The conditioning procedure which we regarded as innocuous" (in 1927) "apparently meant murder to the sheep" (1956, p. 74) because "during the past ten years we have become convinced that all conditioning procedures which are based upon the animal's self-imposed restraint will, if long enough continued, cause that animal to become experimentally neurotic" (1956, pp. 66-67). If *all* animals broke down, then that would, *ipso facto*, be the normal reaction, of course. But Liddell probably had in mind the view that, given sufficient stress, all humans would develop neuroses.

The self-restraint of the trained animal conceals a tense expectancy. For this he uses Head's term "vigilance" which approximates to Pavlov's investigatory reflex. Vigilance, rather than the unconditioned stimuli of shock or food, ". . . supplies the power for both positive and negative conditioned reflex action. If this hypothesis proves to be sound it will lead us to another. We may then suppose that when the capacity for maintaining intense and unremitting vigilance is exceeded (for example, during long-continued and difficult regimens of conditioning) the pent-up nervous tension thereby released will disrupt the operation of the complex and delicate conditioning machinery and lead to chronic states of diffuse or congealed vigilance—experimental neurosis" (Liddell, 1950b, pp. 189-190). Among the further stresses which the experimenter can add to this vigilance, Liddell identifies loneliness, monotony, confusion and overstimulation—examples of which have already been cited. The inhibitory type of neurosis—"tonic immobility"—was regarded ". . . as a state of congealed vigilance. The alarm reaction here appears to be frozen" (1951, p. 145). The excitatory type was regarded as a state of diffused vigilance, though in the most complete statements of Liddell's theory (1955, 1956) the former is now a precursor of the latter.

This brief outline probably does injustice to a theory based on a lifetime of experimental observation and experience, especially as our account of the work which nurtured it has not stressed experiments which are regarded as confirmatory, such as the accidental circuit fault which gave subjects a preliminary shock. Disorders developed only *after* the restoration of the signal to its putative role of tension arouser, unrelieved by the inadvertent shocks. Similarly a rise in tension or vigilance can be seen in indicators such as respiration rate during long conditioning sessions, even in well-trained animals (Liddell, 1951). But it must be said that the theory is not formulated in

precise enough terms to have heuristic value; few testable deductions flow from it. Only Parmenter (1940, 1940a) has made such attempts. He showed that the absence of the restraining harness altered responses in a well-trained sheep. Among other omissions, however, he did not attempt to show whether it was more difficult to precipitate neurosis in untrained sheep by this method of no restraint. Apter (1952) claims to have done so in dogs, though Kaminsky's findings on monkeys (1939) apparently support Liddell. Secondly, Parmenter evolved a method of rapid experimental extinction in one sheep by stopping the conditioned stimulus when the response seemed imminent, thus ending the sheep's "uncertainty" sooner. But since other sheep extinguished without disturbance the support this gives to Liddell's theory is not clear.

The Work of Gantt

The work of the second major researcher in the field, Gantt, is Pavlovian, as might be expected from his training, yet, like Liddell, he is concerned with the problem of the generalization of conditioned neuroses. He, too, appears not to have been primarily concerned with abnormal behaviour at first, but in the course of his conditioning work on dogs accidentally provoked experimental neuroses which appeared to resemble those reported by Pavlov. The accumulation of data on novel aspects of the abnormal behaviour led him to organize his earlier and frequently brief reports (1936, 1938, 1940, 1940a, 1942; Gantt and Muncie, 1941) into his important monograph contribution (1944). This is his "monumental study of his experimentally neurotic dog, Nick (the most meticulous and complete case history of a single animal to be found in the conditioned reflex literature)" (Liddell, 1951, p. 127).

Using dogs as subjects for salivary conditioning with food or acid injected into the mouth as the unconditioned stimuli, Gantt reports on the effect of natural emotional shocks. *Parturition* in bitches disturbs differentiated conditioned responses temporarily. An *accidental disturbance*, comparable to the Leningrad flood, occurred one week-end when some fifteen dogs escaped from their quarters and roamed the building, barking and fighting. One young collie, judged of an inhibitory labile type, showed subdued behaviour and disturbed conditioned responses for a week; in two other dogs studied, the changes were short-lived. Further *fighting*, both accidental and experimentally provoked, caused temporarily altered behaviour. *Restriction* of freedom in a cage eight feet square caused a severe diminution of activity in one young bitch, who died after four months.

Experimental procedures which may give rise to disturbed conditioned responses were next considered.

Conflict of drives was studied by observing the deleterious effect of a female in oestrus on the alimentary conditioned responses of two male dogs. *Conflict of excitatory and inhibitory* conditioned stimuli is a potent source of disturbance. Unlike Liddell, Gantt does not think the restraint involved important. *Changes in conditioning routine*, e.g. the temporal patterning of stimuli (Gantt, 1940), or during experimental extinction, may cause agitated behaviour. But the major part of the work is devoted to the case histories of three dogs who reacted to approximately the same experimental procedures with different degrees of disturbance.

Fritz, a male Alsatian, was a stable, somewhat aggressive animal who developed conditioned differentiation to tones of different pitch. When the discrimination was made more difficult two years later, he showed some disturbance, barking and panting, and a loss of the conditioned responses. More radical measures, such as putting him in a swing and causing explosions, brought only temporary disturbance. After another two years a tactile differentiation was easily achieved, and the responses to auditory stimuli well retained. He died of old age in 1938, after seven years work in the laboratory. At no time did Fritz shun the experimenter or the experimental room, always ate food offered there, and displayed normal sexual activity. The second dog, Peter, was a male beagle, active and playful. In 1931 though he formed rather unstable salivary responses to the same tones as Fritz quite quickly, he barked somewhat. The initial stages of the same discrimination were successfully accomplished; when made more difficult, however, he howled, refused food in the experimental room, and had to be coaxed to enter it. Next year all conditioned responses disappeared and he had to be forced into the room. He became quieter later, resumed eating and, while the use of the swing and explosions produced disturbances, short rests from work restored normal behaviour. After a further rest of one and a half years, he was quiet and gave conditioned responses. He was killed in a fight in 1936.

The case history of the celebrated Nick is longer—he was studied for twelve years—and shows even more severe disturbance of behaviour. He was a male mongrel, about three years old, and active and playful when work began in 1932. "Nothing was noted that impressed one as remarkable; in fact he was selected with Fritz and Peter for laboratory work, as being, according to general appearances, normal" (Gantt, 1953a, p. 77). He was more restless than most dogs during adaptation to feeding in the experimental room, and slow in showing the conditioned salivary response, with restlessness and whining. When the auditory differentiation was introduced he refused food and

showed defence reactions. A rest restored food acceptance, but with an increase in the difficulty of the discrimination, he refused it again (October, 1932) and he "... continued to refuse it practically during his whole laboratory life ... in spite of over 10,000 presentations of (the conditioned stimulus) and food" (Gantt, 1944, p. 53). His negativism in this respect contrasts with Fritz's behaviour, and persisted despite an increase in hunger drive. The added restraint of a Pavlov harness did not affect him.

In the following year all conditioned responses failed, and a definite physical progression in the inhibitory effect of the experimental room was observed; Nick would eat the more readily the farther he was away. In the room he showed a stereotyped restlessness, frequently seen afterwards, whenever he was released from the apparatus. It consisted of rushing around, jumping up on the table and off it again, and barking at, fumbling in his mouth, and dropping, the uneaten food. The additional strain of the swing and the explosions did not exacerbate the behaviour, but neither did injections of cortin nor a three weeks rest from experimentation improve it. A further rest of two years (1934–1936) caused only a slight improvement as judged by his eating and the temporary restoration of conditioned responses. To ameliorate his condition, Nick was fed the whole of his meat ration in the experimental room every day for seven months in 1936. This attempt at therapy failed; indeed, Nick showed fresh abnormalities, involving other physiological systems. Disturbed respiration took the form of "loud, forced breathing," which was heard whenever he was excited, especially when approaching the experimental room or people connected with the experiment. The disturbance in social behaviour thus demonstrated is characteristic of Nick; Gantt repeatedly noted that he was friendlier towards strangers than towards anyone associated with the experimentation on him. Other disturbances became apparent at the end of 1936; Nick would start urinating when being brought to the experimental room where the frequency was as much as twenty-five times in thirty minutes. This exaggeration of a male canine habit was unaffected by punishment. Concurrently, abnormal sexual excitation—as judged by penile erection—was observed during conditioned stimulation, or even occasioned, apparently, by the experimental setting itself. These persistent sexual erections contrasted with the occasional short erection seen in young male dogs, especially in spring or when excited.¹ A further piece of unusual behaviour, noted around this time and which persisted for at least six

¹ Both the urinary and sexual abnormalities occurred after a bitch in oestrus had been used in the experimental situation in order to test the effect of normal sexual excitation upon Nick's other abnormal signs.

years, was Nick's habit of reacting—with defence movements, gazing, etc.—towards the place where the auditory signal *previously* came from, after its location had been changed. Pavlov (1941) mentions a similar occurrence in an experiment by Filaretov.

The rest of Nick's history—he died in a fight in 1944—was devoted to a study of his abnormalities, which did not proliferate further but fluctuated in intensity. New methods of investigation and therapy were tried. Generalization within the experimental situation was demonstrated by the prompt conditioning of Nick's responses when a new stimulus, a visual one, was given in association with the tone. Wide generalization outside the situation was observed, especially on Gantt's farm in the country, where Nick was kept for periods of two and seventeen months during 1937 and 1939–41 respectively, in that the particular food given as reinforcement in the experimental situation was consistently refused there, and sexual erection, pollakiuria, disturbed respiration and a marked increase in heart rate were sometimes observed at the approach of people previously associated with the experimentation, or even members of their families.

The rests in the country were therapeutic to the extent that afterwards the anxiety and stereotyped responses in the experimental room were lessened, though after the longer one this may have been part of a general improvement due to advancing age or to a change in method. In 1942 a motor conditioned response, using shock to the paw as the unconditioned stimulus was developed, to see if altering the response involved would prove beneficial. Unfortunately, the experimental room was also altered. The change was striking: the positive conditioned response to a tone (though not the same one as originally used) was developed readily, and some progress towards differentiation was even made. Moreover, Nick was quieter and without the sexual and respiratory disturbances which could, however, be reinstated on visits to the old experimental room. The new routine had, therefore, “. . . extinguished the pathological anxiety reactions to the specific auditory signals but it had not abolished the effect of the total environment of (the former room)” (Gantt, 1944, p. 99), which latter is hardly to be expected in view of the change in location.

The therapeutic effect of normal sexual activity outside the experimental situation was investigated by caging Nick with a female in oestrus. Less anxiety was displayed and measurement of cage activity showed a decrease. Sexual activity inside the experimental situation, however, showed a reciprocal relation with the anxiety reactions. In the presence of an oestrous female or during artificial sexual stimulation by means of electric stimulation of the external

genitalia, the conditioned signal produced no reactions and its effect was diminished for some time afterwards if ejaculation had occurred. On the other hand, the experimental environment affected the sexual reflex itself. In an attempt to quantify this effect on the latency and duration of Nick's sexual response to the artificial stimulation, control measures were taken outside the experimental situation and also upon two normal dogs in both situations. The data, though inadequate for satisfactory analysis, suggest that the experimental room decreased Nick's latent period for ejaculation and duration of erection, whereas there were no marked changes in the control dogs. The effect of alcohol on Nick's disturbed behaviour was also observed (Gantt, 1940, 1952) and appeared to abolish the anxiety responses to the tone temporarily. Nick showed a greatly diminished sensitivity to the effects of adrenalin (Gantt and Freile, 1944).

In further contributions (1953; Gantt and Dykman, 1957) Gantt briefly describes another dog, V 3—“the most persistently neurotic of any dog we have had” (Gantt, 1953, p. 154). This male French poodle, born in the laboratory, had always been shy and fearful (Gantt, 1953*a*) and showed a stereotyped pattern of activity in rushing in and out of the experimental room, but a passivity on the experimental stand when limbs were retained in unusual positions in which they were placed, and the dog was apparently insensitive to pain. Since this occurred without any conditioning procedure beyond the use of restraint, it suggests a spontaneous, as opposed to an experimental, neurosis (*see* Fuller, 1947). The only experimental work reported was a study of the effects of alcohol on V 3's sexual reflexes, which, atypically, could only be elicited under the influence of this drug. His frightened behaviour was also thereby alleviated.

Gantt, though he does attempt to quantify certain behaviour, shares with the Cornell group a tendency to present inadequate data which have not been subjected to proper analysis, making unequivocal conclusions impossible. Thus most of the work reviewed here is observational or even anecdotal in character. He has a distressing technique which may be termed “evidence by appeal to the bystander.” One example will suffice: he deems it worthy of report that “. . . two boys aged 7 said apropos of his (Nick's) raucous breathing, ‘Gee that dog certainly does breathe funny.’” (Gantt, 1944, p. 102). Moreover, the design of the experiments undertaken is not beyond criticism, as has been indicated. Gantt's use of the longitudinal approach with Fritz, Peter and Nick is a praiseworthy contribution but would have been more informative if all subjects had been from the same litter, or at least from the same breed. Again, one has the impression of an experiment turning into a study of neurosis by accident, since

Nick was originally selected for his apparent normality. Having shown disturbance, he was used, one has the further impression, mainly for demonstration purposes, and the therapeutic aspects perhaps not explored as thoroughly as otherwise might have been the case. On the other hand, Gantt in his Foreword (1944) doubts if the understanding of conditioning in physiological terms, despite the important contributions which he has made and continues to make (1957), is sufficiently advanced to evaluate abnormal behaviour in such terms. Hence his recourse to description in "behavioral terms." But there are, and indeed were in 1944, grounds for believing that behavioural measures, especially in the laboratory, may be objectified and quantified.

Hebb's criteria are easily applied to Gantt's work. Thus, Nick's behaviour was frequently *evaluatively undesirable*, e.g. his refusal of food when hungry, and was markedly *emotional*, judging by overt signs. We know from the autopsy report Gantt gives (1944) that he had *no gross neural lesion*. The persistence of disorders is strikingly well established in Nick's case, as is their *generalization* to situations other than the experimental. Their generalization to systems other than those especially concerned in the original conditioning appears as confirmation of their abnormal character, but there are dubious features about this as will be shown later. Considering two of Hebb's ancillary criteria, the *change from a previous base-line* is well seen in Nick though less well in V 3, just as is the presence of *trauma or conflict* in their history. It is in connexion with the criterion of *statistical abnormality* that reservation must be made. Gantt does not say from what total these two cases came; it is clear it must have been a substantial number, thus yielding a figure probably less than the 33 per cent implied by his presentation of the three cases of Fritz, Peter and Nick, only one of whom became neurotic. On the other hand the selection of these three for their apparent normality originally may have depressed this figure, and we are thus left in doubt. Nevertheless, we may say that Gantt's work, while not entirely satisfactory on all counts, comes closest of those so far reviewed in this chapter to meeting Hebb's criteria of abnormality which can probably be related to human neurosis.

Gantt's theoretical views (1953) employ two fundamental concepts: "schizokinesis" and "autokinesis." The former, originally called "dysfunction," implies a cleavage in response between the emotional and visceral systems and the skeletal musculature, and has its origins in observations, especially of cardiac function, suggesting that cardiac conditioned responses are formed more quickly than motor ones, are of comparatively greater intensity, and are more resistant to extinction (Gantt, 1942a, 1946, 1948; Gantt and

Hoffman, 1940; Gantt and Muncie, 1941; Gantt and Traugott, 1949; Gantt and Dykman, 1952, 1957; Gantt, Hoffman and Dworkin, 1947; Gantt, Gakenheimer and Stunkard, 1951; Robinson and Gantt, 1946, 1947; Owens and Gantt, 1950). Consequently large emotional and endocrine responses may persist after the need for the appropriate accompanying motor response has passed. "Autokinesis" refers to the internal development of responses on the basis of old excitations, as seen in the spontaneous restoration of extinguished conditioned responses and the appearance of signs of experimental neurosis long after the causal conflict has been removed.

Gantt's theoretical formulation has some of the same characteristics as Liddell's. It is too imprecise to provide testable deductions, and some of the facts it endeavours to subsume are insecure. This especially applies to schizokinesis as is seen in a well-designed study with proper statistical procedures by Dykman, Gantt and Whitehorn (1956), previously reported in brief (Dykman and Gantt, 1951, 1951a). Four dogs were each given motor conditioning (leg flexion) to three intensities of shock as the unconditioned stimulus. In addition to measures of latency and amplitude of the motor response, cardiac and respiratory records were taken, though only the analysis of the former is reported. The results clearly show the development of a differential motor response—larger and swifter, usually at a satisfactory level of significance, the greater the shock stimulus, and a differential cardiac conditioned response was also detected. However, the cardiac conditioned responses did not develop more quickly than the motor ones, and the differentiation observed did not proceed faster in the cardiac than in the skeletal system. Unfortunately, no systematic study of the extinction of the conditioning was reported. The authors do say, however, that after a month two subjects showed unimpaired differentiation, presumably of both motor and cardiac responses. These findings from a well-designed and adequately analysed experiment run counter, therefore, to expectations based on the schizokinetic principle, itself elaborated from data from experiments, which, as judged by the brief reports cited above, were less well controlled. This suggests that the concept of schizokinesis itself may need revision.

The Work of Masserman

The contribution of the third major American worker in the field of abnormal animal behaviour, Masserman, is based on a psychoanalytic interpretation of behaviour, and so differs markedly from that of Gantt and Liddell, both of whom began as Pavlovians. An example of the lengths to which Masserman is prepared to go is his interpretation of Yerofeeva's experiment, in which shock was used as a conditioned

stimulus (see page 728), as a demonstration of animal "masochism" (Masserman, 1943, pp. 176-177; Masserman and Jacques, 1948). This approach is one to which the writer is unsympathetic; the reader is therefore, cautioned against this bias. Moreover, Masserman is avowedly anthropomorphic (1942, pp. 345-346) in a way which is rightly eschewed nowadays.

Masserman's research is presented in numerous articles, but especially in his book *Behavior and Neurosis* (1943), which also reports on his work in experimental neuropsychology which will not be discussed here. For his experiments on neuroses in cats, less fully reported earlier (1942), he used a learned motor response to a warning stimulus. This response, the lifting of the lid of a food trough to secure food, had been employed by Sutherland and others in work on the pig (see page 736), but more extensively by Dworkin and his associates, including Sutherland, at McGill University in Montreal, in a series of experiments on the auditory capacities of the dog and the cat (Dworkin, 1935, 1935a; Dworkin, Seymour and Sutherland, 1934; Dworkin, Katzman, Hutchinson and McCabe, 1940; Davis, Dworkin, Lurie and Katzman, 1937; Dworkin, Baxt and Gross, 1942). As several cases of experimental neurosis eventuated from the use of this method, some account of Dworkin's work—itsself almost a major contribution to the field—will serve as an introduction to that of Masserman.

The cats were restrained in a cage (large enough to allow free movement) in which there was a food box into which a piece of food was automatically delivered by a rotary feeder, after an auditory signal had sounded. The arrangements for dogs were similar, except that they were confined in a Pavlov harness before the food box. The lifting of the lid of the food box was regarded as the response in the trained animal, and in studies of auditory thresholds indicated that the subject had heard the tone. In discrimination studies, opening the lid indicated that the subject had recognized the positive signal—the negative one not being followed by food. Both these procedures gave rise to disturbances in both species (Dworkin, 1938, 1939). Tests of pitch discrimination involved increasingly difficult judgements as the positive and negative tones were made more alike, and in two dogs caused a progressive inhibition of the alimentary response, failure to eat the food offered, even when very hungry, and restlessness, barking and whining in the experimental situation. One dog developed a marked flexion of the left foreleg, obviously thinking it was at Cornell, not McGill! Periods of rest did not restore responses, but no unusual behaviour was observed outside the experimental situation. In cats disinhibition was observed; they responded to the negative signals as well as the positive. However, they

never refused food, nor showed any other sign of disturbance.

The tests of auditory acuity involved presenting the subjects with very weak tones: four out of seven dogs showed progressive inhibition of response, first to the weak tones, but later to all stimuli, so that after four to six months two of them remained stock still in their harness, not asleep, but insensitive to all but unusual stimuli. Rest had little effect, but drugs (including alcohol, Sodium Amytal, Avertin and Nembutal) had beneficial effects in certain cases (Dworkin, Bourne and Raginsky, 1937, 1937a; Dworkin, Raginsky and Bourne, 1937). In the reactions of thirty-four cats to the same procedures, Dworkin distinguished three groups. Firstly, nine animals went through the whole experiment with no disturbances. Secondly, a group of four cats who developed inhibition to superthreshold tones after being exposed to faint ones, and showed stereotyped movements and attempts to escape. The third group, the remaining twenty-one cats, displayed a lack of restraint so that they opened the lid not only to all stimuli but constantly in between stimuli as well ("interval activity"). Rest restored the trained responses, at least temporarily. Three cases of more profound disturbances in cats are reported separately by Dworkin, Baxt and Dworkin (1942). In one cat, which had been subject to cochlear damage, the onset of the interval activity was preceded over a period of two years by restlessness and vomiting in the experimental box on at least five occasions. The absence of gastro-intestinal disorder was confirmed by necropsy, and the cat ate well elsewhere. Two further cats urinated in the box, one of them alternating with periods of interval activity, and also displaying changed behaviour outside the experimental situation. He became aggressive, and resisted coming for testing. Rest helped little, but a different experimental room and the restoration of superthreshold stimuli were beneficial. In each case bromide therapy afforded little relief. Only these last cases evidence any generalization, and so approach Hebb's criteria for abnormal behaviour. Dworkin, however, believes the disturbances of behaviour to have been more serious in dog than cat, and suggests that this supports Liddell's emphasis on the importance of restraint in the production of neurosis, since the dogs were confined in a harness whereas the cats were not. The confounding of the species difference with this variable clearly vitiates any such conclusion.

A study using the same alimentary motor reaction specifically for the production of neurosis in cats is reported by Dimmick, Ludlow and Whiteman (1939). After six cats had been trained to lift the lid of the food box on signal, they were shocked whenever they lifted it *between* the signals. They stopped feeding altogether, whereupon the presentation of the signal

itself was associated with a "punishing shock." It is not clear how often this was done nor whether all subjects were treated alike or not, but the descriptive results presented show that the anxiety responses thus established generalized to the experimenters and to the cats' living quarters, and persisted despite increased motivation and a rest of ten days.

Masserman's technique (1939) is very similar, except that he also used as an aversive stimulus a blast of air to the side of the animal's head, sometimes in combination with shock, sometimes alone. It was physically harmless but made a "rather loud, sudden noise" (Wikler and Masserman, 1943), elsewhere described as "explosive" (Masserman and Jacques, 1948). Masserman's work suffers from the defects of insufficient control and inadequate quantitative analysis which it has been so frequently necessary to mention in this review, but has an ingenuity about it which compels attention. Nevertheless his description of it in his monograph (1943) is usually unsatisfactory. There is no standard experimental procedure; the intensity of the stimuli used is not specified, and the results are described in the form of a "typical" subject's reactions. Even these are sometimes internally self-inconsistent, larded with alliterative anthropomorphisms (the cat ". . . came up to the food box and muzzled it meditatively . . ." (1943, p. 69)), and contain statements for which no evidence is offered (" . . . many of these animals showed chronic disturbances of pulse and respiration . . ." (1943, p. 67)). Background data—age, past experience, even sex—are lacking, and there is confusion over the number of subjects and experiments, eighty-two being mentioned in one place as the total number of cats used, though other figures relating to the number given shock, blast or both suggest a total of one hundred and six. The blast was favoured as a traumatic stimulus on the grounds that it was "psychologically more significant." Certain control observations were made which suggest that hungry cats trained to lid lifting on signal did not become neurotic if their path to the box was blocked, or the lid locked, or, what Masserman picturesquely calls "fractional frustration" (partial reinforcement) instituted. As might be expected, the feeding response was extinguished in the first two cases and very persistent in the third (Jenkins and Stanley, 1950). More crucial are the observations that the conditioned light and bell signals alone or in combination with the air blast were not disturbing, and it is claimed that the blast, after such a combination, could be used even when a cat was feeding, without ill effect, but the procedure used is unclear from the description. Even more important, in view of the criticisms of this work to be discussed, is that no such control observations involving the use of the shock are reported.

The behavioural responses to the imposition of an air blast across the food box, or the electrification of the floor or both, just as the animal opened the lid, showed individual differences. Usually there was a marked fear response, failure to feed from the box any more, and evidence of conditioned fear reactions to the signals for the delivery of food. These manifestations could be increased by pushing the cat towards the food box and persisted for months, but were, Masserman claims, at their height after three days, a time he identifies (though without supporting evidence) as coinciding with maximal hunger in the cat. The use of air blast with two dogs in a larger box gave essentially congruent results.

Evidence for the generalization of these responses is adduced from the changed "personalities" of some cats and from the fact that both dogs developed resistance to entering the apparatus. In addition, Masserman and Siever (1944) showed that the dominance order in groups of four cats—established by allowing them to compete at the food box—was disrupted by the fear conditioning. The least dominant cat could be transmogrified by successively affecting animals higher in the hierarchy. The emergence of aggression towards the competing cat is said to depend on previous experience of dominance, but this does not seem to follow from the carefully documented report on, however, only one of the groups of four.

Masserman is especially concerned with possible therapies of experimental neuroses and their relative efficacy. This enterprise is doomed to failure in any objective sense, of course, by the absence of quantification of the intensity of the disturbances induced, and of an untreated control group to assess spontaneous recovery. The techniques he applied were rest from experimentation, which had little effect, and others designed to abolish the "motivational conflicts" (between hunger and fear) which Masserman believed he had set up in his cats, thus reducing "their aberrant behavioral expression." Specifically they included: reducing the hunger drive by feeding before an experimental trial, increasing it to starvation point, reassuring and petting the cat, and forcing it towards the food box. Interestingly, it seems from Masserman's description that the movement of the barrier by which this was done developed into a conditioned signal for feeding in several animals. The technique of imitation—allowing a well-trained non-traumatized cat in the cage with the neurotic one—was ineffective as therapy, but what Masserman calls "working through," more so. This involved prior training so that the cat itself initiated the feeding signals by pressing a switch. After the fear had been induced such cats began feeding again sooner than ones not so trained.

Masserman completes his monograph on experimental neurosis with a comprehensive, if polemical, review of the pertinent literature. It is bewildering to find familiar studies being cited in support of psychoanalytic notions completely at variance with their authors' intentions. Fears tend to become "phobias," repetition is always "compulsive" and the reappearance of an earlier habit, "regression." He is critical of conditioned reflex concepts, preferring a theoretical position akin to McDougall's "hormic psychology." Thus, Anderson and Parmenter's (1941) observations "... all but beg for more dynamic and meaningful interpretations" (1943, p. 120). His own position is expressed in four "principles of behavior," basic to his "biodynamic system." They are very general statements, some of which are widely acceptable, and comparably devoid of heuristic value. Behaviour is motivated (first principle), adaptive (second principle), symbolic (third principle) and, fourthly, subject to "vicissitudes," "... when the meanings of the perceptive field become confused or the motivations conflictful." Then behaviour becomes "hesitant, vacillating, inefficient, inappropriate, or excessively symbolic or substitutive," that is, neurotic. To the extent that the above adjectives fit the observed behaviour of his animals, Masserman regards that behaviour as neurotic, and the principle itself, by some naïve logic, validated. Beach's comment applies: "We do not intend to deny the possibility of a close relationship between the psychological mechanisms involved in human neurosis and the behavioral deviations which have been described in some animals. But it is very important to hold in mind the fact that this problem is unsolved and until the solution is available egregious extrapolations are unwarranted and dangerous" (1953, p. 376).

The extent to which the behaviour Masserman reports can be described as abnormal can be judged as before by reference to Hebb's criteria. It was not *statistically abnormal*, and neither its *persistence* nor its *generalization*, in terms of situations or systems, has been satisfactorily demonstrated. It is not even clear that it was *evaluationally abnormal* from the cats' point of view. The absence of *gross neural lesions* may be presumed, and the ancillary criteria of *change from a previous base-line*, and the presence of *trauma or conflict* certainly met. Indeed, the last two provide the rationale for the whole experimentation. But of all the major studies noted so far, it must be said that Masserman's least approaches the criteria adopted. The true nature of the behaviour described will be suggested, after some subsidiary work has been reviewed, and some repetitions described.

In a series of studies Masserman has investigated the therapeutic effects of various drugs, of electroconvulsive shock and of brain lesions on the disturbed

behaviour. Some of the techniques used are an advance on his earlier purely observational methods. Thus, in a study of the effects of alcohol (Masserman, Yum, Nicholson and Lee, 1944; Masserman, Jacques and Nicholson, 1945; Masserman and Yum, 1946) six-point rating scales covering seventeen aspects of behaviour (e.g. reactions to experimenter, to other animals, to a caged mouse; autonomic changes; activity, etc.) were developed and applied to twenty-one cats to arrive at an "index of neurosis," said to reflect changed behaviour after air blast or shock. The use of statistical techniques such as correlation, regression and significance tests on these data cannot be unreservedly welcomed in the absence of indications of the reliability and validity of the scales. The results suggest that if given before the introduction of the aversive stimulus, alcohol prevents the development of disturbed behaviour, though the cats developed a dislike for its taste, presumably because of a conditioned association with the fear stimuli which always followed its ingestion (cf. the rationale of conditioning pharmacotherapies of alcoholism (Franks, 1958)). This contrasts with experiments where the drug was given *after* the fear responses had developed and afforded relief from feeding inhibitions, etc., in proportion to the dosage given. In this case the development of a preference for milk and alcohol as opposed to the plain milk previously preferred could be demonstrated. No "addiction" developed.¹ The preference was thus "... a learned adaptation contingent upon intercurrent neurotic stresses, and reversible when these stresses were resolved" (Masserman and Yum, 1946, p. 51). Macleod (1953) has criticized Masserman's interpretation, and Conger's careful work (1951) on the effect of alcohol on rats in an approach-avoidance conflict situation (Miller, 1944, 1951), which showed that the specific effect of alcohol is to reduce the avoidance response to shock, leads him to question Masserman's formulation also. However, Miller (1956) has been able to repeat neither Masserman and Yum's nor Conger's findings.

An earlier study on the effects of morphine and one not using the Masserman-Yum scales (Wikler and Masserman, 1943) gave results comparable to those found with alcohol. Four cats showed relief from anxiety and one of them did not display it again. A fifth, however, was not relieved by large, and finally fatal, doses. In studies of electroconvulsive shock using sine wave (Masserman and Jacques, 1947) and square wave (Masserman, Arief, Pechtel and Klehr, 1950) currents, it was shown that electroconvulsive shock abolished the neurotic response as rated, but also disorganized the normal feeding responses thus

¹ See Stainton (1943) for a review of the literature (mostly anecdotal reports) on addiction in animals.

restored. Further work on the effect of brain lesions used twenty-three cats (Masserman and Pechtel, 1956), but a fuller report by Pechtel, Masserman, Schreiner and Levitt (1955), on the effects of lesions on nine animals operated on before being subjected to shock compared with eight operate controls not traumatized, shows that the former group had greatly diminished in their fear reactions to stimuli, including odours (Masserman, Pechtel and Schreiner, 1953), which had served as signals for shock. In most cases, however, residual muscular tension was still detectable, and the cats were rated as having become significantly more aggressive to others. For this work, the experimental box had been modified to include two upper compartments containing the switches for initiating the feeding signals, thus permitting a series of problems which, from the curves given, can be graded in difficulty. All animals had forgotten these routines post-operatively, and had to re-learn them.

Thus, Masserman has energetically applied the technique he had adopted to study a series of agents which might be expected to modify the disturbances in behaviour produced. Despite the slightly greater sophistication of the experimental methods used, the results have not been especially precise, though in most cases it has been shown that the disturbances have been attenuated (Masserman, 1951, 1953). The value these investigations have to topics other than neurosis, that is, electroconvulsive shock, and psychosurgery, has not been stressed here, and reference should be made to Chapters 16, by D. Campbell, and 15, by R. A. Willett, respectively.

Masserman's interpretation of his basic work has been challenged by Watson and by Wolpe. Watson (1954) trained seventeen cats to press a switch to activate feeding signals. Air blast or shock was applied at the moment of feeding, and the learned response was disorganized. However, one of two stable behaviour patterns soon emerged; either the cat resumed feeding or withdrew from the food altogether. No changes in behaviour in the home cages were observed. The effects of exposing ten control subjects to the aversive stimuli gave "a different acute reaction" which soon wore off, so that the stimuli were tolerated later. While noting that his work does not repeat Masserman's exactly—in particular, the cats lived in spacious group cages—Watson suggests that the behaviour observed could not be considered abnormal as it was neither chronic, nor maladaptive (Hebb's criterion of evaluationally abnormal). The two distinct patterns of behaviour which evolved are both considered adaptive—the resumption of feeding to avoid starvation, and the refusal to do so to avoid injury, which for all the cat knew may have resulted in death. Unfortunately, the

value of this contribution is lessened by the serious deficiencies in the presentation of even the observational data it offers, brief descriptive statements alone being given.

Wolpe starts from a more seriously critical standpoint than is implied by Watson's simple repetition. He notes (1952) that both Masserman, and Dimmick, Ludlow and Whiteman, in using the learned alimentary response, fail to control for the effects of the noxious stimuli apart from its effects on that response, and so couch their explanations of the changed behaviour in terms of irrelevant motivational conflicts. His own experimentation is designed to remedy this deficiency. He used twelve cats in an apparatus like Masserman's; six were trained to feed on hearing a signal and then given a shock (air blast was not used) when attempting to do so. The control group of six was not trained to feed, but given only shocks, preceded by the signal, in the same box as the others. The number of shocks given was not, however, equal, the control group receiving more.

The results are presented descriptively. All animals showed resistance to being placed in the cage, and signs of anxiety especially muscular tension and mydriasis, when inside; all refused to eat there even after one to three days starvation. On occasion howling and rapid respiration were observed, and all these signs of fear were intensified by the auditory signal. One cat developed a tic reminiscent of abortive jumping which may have had its origin in his leap out of the top of the cage, left open inadvertently, when first he was shocked. An ingenious attempt was made to observe the generalization of the responses to the shock by the use of different rooms—a method used by Liddell (1944, 1956) and by Gantt (1944). Wolpe used three rooms which "... seemed, to the human eye and ear, to have decreasing degrees of resemblance to" the experimental room. The signs of anxiety to the conditioning signal were weaker in these rooms to the extent to which they differed from the experimental room.

In attempting therapy for five of the anxiety responses, Wolpe also used the three rooms. A room was found in which anxiety was sufficiently attenuated to at all. After feeding in this room, a cat was moved to the one next higher in the scale of the experimental room, and so on feeding in the latter room itself. Other therapies achieved involved feeding the cats from the box or forcing them to the food. Elimination of anxiety to the signal was effected in two cats by gradually increasing the signal to the point of

subjects, a brief sounding of the signal was used to herald the presentation of a meat pellet. It was thus converted into a conditioned alimentary signal—for the second time in the case of the group originally trained in this way. After these procedures the auditory signal had no effect whatsoever.

Despite the lack of adequate quantification of the phenomena observed, Wolpe's experiment is superior to Masserman's because of the careful control of the variable relating to the effect of the aversive stimulus, independently of its effect on learned responses and he has replied sharply (1954) to Masserman's failure (1954; Masserman, Gross and Pechtel, 1954) to recognize this fact. He bases himself on a rational theory of learning and seeks to utilize it to devise therapies for animal and human anxiety (Wolpe, 1958) and to account for some aspects of experimental neurosis, as will be shown later. But his interpretation of the changes in behaviour produced in his cats as experimental neurosis is less satisfactory. His definition of experimental neurosis as "... unadaptive responses that are characterized by anxiety, that are persistent, and that have been produced by behavioural means . . ." (Wolpe, 1952, p. 243) is reminiscent of, though less comprehensive, than Hebb's. His criterion of unadaptiveness he considers to be met because the cats refused to feed even when no further shocks were to be given. But how were the subjects to know this? As Watson notes in connexion with the same problem: "It does not seem possible to regard the cats' behaviour as maladaptive without presupposing capacities to evaluate danger which cats may not possess" (1954, p. 345).

Schefflen (1957) has also studied the extinction of a fear response in cats, using air-blast as the noxious stimulus to break up a previously learned alimentary response. She used two different boxes, and showed that extinction of the fear response in one occurred sooner if the original training and aversive stimulus had occurred in the other. No suggestion that the fear responses observed are abnormal is made by this author nor by Lichtenstein (1950). He produced an extinction of feeding in hungry dogs, who had been trained in a Pavlov harness. He found that a group of dogs, shocked when actually eating the food, resumed feeding sooner than three dogs, shocked when not eating, and a group of dogs, shocked on the majority of occasions when only presented with the food. Lichtenstein also observed catalepsy, tremors (as in Wolpe's cat¹), and autonomic signs of anxiety. The dogs always struggled and fought in the box, and the dogs refused the food used in the box as offered in their home cages, but not when offered orally. Excited or aggressive behaviour was also observed.

other examples of tics in

The feeding inhibitions were relieved in most cases by prefrontal leucotomy, while a control group subjected to sham operation maintained theirs for one to three weeks (1950a).

Lichtenstein identifies the complex of behaviour observed in his experiments, of which the actual feeding inhibition is only a part, as one of fear or anxiety, and develops a closely reasoned argument against calling it experimental neurosis (1950). Despite differences in the details of the results obtained by these workers studying feeding inhibitions,¹ it seems clear that what the investigators using alimentary responses in dogs and cats in the experiments discussed above have been observing is the conditioned emotional response or C.E.R. (Watson and Rayner, 1920; Brady and Hunt, 1955). Masserman would almost certainly disagree with this appraisal, as he has specifically denied that the responses he has elicited are conditioned fear responses (1950; Masserman and Siever, 1944), basing himself partly on the argument that "... the reactions of anxiety and patterned defense began to spread to other situations only remotely or 'symbolically' associated with the neurotogenic one—a process of 'irrational generalisation' that every clinician will recognize as characteristic of human neuroses" (1950, p. 56). Masserman's lack of confidence in the often demonstrated normal generalization of conditioned fear receives melodramatic expression in his claim that, in the absence of dynamic, motivational conflict, "... human neuroses would quite literally be confined to people who had either been caught in an electrical short-circuit or struck by lightning at the moment they were pushing an accustomed button to secure food from an automat" (1954, p. 222).

It is not possible, of course, to accept Masserman's assertions regarding the nature of the behaviour he has studied, couched as they are in subjective terms, without the backing of quantification, control and appropriate analysis. Furthermore, the appellation of experimental neurosis is especially inapposite here, since, as we have seen, there is no satisfactory evidence that the responses are abnormal, even at the level of the species in question. The application of this conceptual framework to the field of psychopharmacology (Jacobsen and Skaarup, 1955) is therefore unfortunate, especially now that the parameters of conditioned

¹ In all likelihood, many of these differences are attributable to differences in technique used. Thus, in the experiments using shock as the aversive stimulus, its strength, nowhere precisely specified, was probably weakest in Watson's case, since many of his cats resumed feeding, the next strongest in Masserman's since he does note that five cats were at first unaffected by it, and the strongest in Wolpe's and Lichtenstein's, since all animals were affected by it and the disorders were persistent. Two further repetitions of Masserman's work using cats have been reported in abstract, Yacorzynski (1946, 1948) reaching conclusions at variance with Masserman's, while Cain and Extremet (1957) do not.

fear are more fully understood and better methods of quantification available.

Masserman's further work has been on primates. It will not be reviewed in detail, not only because a promised monograph has not yet appeared, but also because the methods used and the results reported parallel those for cats. The apparatus used is a larger and more complicated version of that previously described, and the aversive stimuli used with monkeys included electric shock, a water jet, ". . . or, more significantly, the sudden appearance of a toy rubber snake in the food box" (Masserman and Pechtel, 1956). The reactions claimed as a direct and exclusive reaction to the sight of this snake, as compared with other moving toy or mechanical objects (Masserman and Pechtel, 1953, 1953*a*) are almost incredible. They include, as well as the feeding inhibitions met with in the cat, muscular and gastro-intestinal dysfunctions, sexual deviations, and behaviour boldly identified as "hallucinatory" in two monkeys who appeared to eat "imaginary" pieces of food. The evidence presented is neither sufficiently detailed nor well-controlled to be convincing, and the unsubstantiated claims of a psychoanalyst to have discovered in so obvious a phallic "symbol" the one object to cause persistent experimental neurosis is necessarily subject to a pardonable scepticism. This is reinforced by lack of experimental evidence for the generality of this finding. Thus, Jones and Jones (1928) showed there is no innate fear of snakes in a human infant, and Rand (1941, 1942) found that the fear of a dummy snake is soon extinguished in certain species of birds. Moreover, in monkeys the conditioned avoidance response based on shock is subject to the usual—if slow—experimental extinction (Waterhouse, 1957).

Masserman has made some use of that neglected sensory modality, smell, and has demonstrated (Masserman, Pechtel and Schreiner, 1953; Pechtel and Masserman, 1954; Masserman and Pechtel, 1956*b*) that odours are not so readily learned as conditioned signals for food as lights or sounds, but when associated with fear stimuli they become potent, and generalize widely to other smells. The effect of brain lesions and drugs on the monkeys' behaviour has also been reported. Again using rating scales, now said to have high reliability, Masserman and Pechtel (1956) have shown that lesions in the amygdaloid nucleus appear to have a large effect on the disturbed behaviour. The large number of variables liable to affect these findings is rightly stressed. No marked effects of drugs were found (Masserman and Pechtel, 1956*a*), and, indeed, this paper is more notable for the careful attempts to analyse some parameters of the behaviour observed. Thus age is shown to be important, younger monkeys being more susceptible to disturbance than older ones. The largest correlation,

however, is that between "number of traumata to produce neurosis" and "spacing of traumata," which is negative and about 0.8. Confirmation of one of the fundamentals of learning theory—the greater efficiency of spaced, as compared with massed, practice—is unexpected from such a quarter!

While the extension of Masserman's work to another species is to be welcomed, many of the criticisms made of his earlier work on cats are unfortunately still applicable. Penrose's comment that "the implications of Masserman's work do not seem to be clear at present" (1953, p. 77), still holds.

While Masserman is alone in having deliberately attempted to produce experimental neurosis in primates, several reports of the accidental or spontaneous occurrence of neurosis are found. The most celebrated of these is that of Jacobsen and his co-workers, the early reports of which (Jacobsen, 1935; Fulton and Jacobsen, 1935) inspired Moniz to initiate the technique of prefrontal leucotomy (Crawford, Fulton, Jacobsen and Wolfe, 1947). One of two chimpanzees frequently had a temper tantrum when it made a mistake on a test of delayed reaction, in which the animals were trained to choose between one of two cups under which they had seen food hidden, but which had been out of their sight in the interim. As the task was made more difficult, this behaviour became more frequent, no responses were made and the subject had to be forced into the experimental cage. "It was as complete an 'experimental neurosis' as those obtained by Pavlov's conditioned reflex procedures" (Jacobsen, Wolfe and Jackson, 1935, p. 9). Be that as it may, the disturbance was cured by feeding, petting and simplifying the problem. After one frontal area of the cortex had been removed, the same events occurred on retraining and were treated in the same way. But after the second frontal area was removed a marked change was noted. The animal no longer became upset over errors, and willingly came to the experiment despite them: "It was as if the animal had joined the 'happiness cult of Elder Micheaux,' and had placed its burdens on the Lord!" (1935, p. 10). Hence the interest of psychiatrists.

Wendt (1934) also reports "'blow-ups' (Pavlov's 'experimental neurosis')" in one baboon during training to delay an alimentary reaction, but since they did not occur when she had been fully trained, they were probably examples of the upsets likely to disturb the smooth progress of conditioning. According to Dworkin (1939) it is difficult to distinguish such disturbances from "border-line neurosis," except by their duration. Yerkes (1943) relies heavily on this distinction: he identifies the disturbance in behaviour of a chimpanzee which bit him when she failed in a difficult problem-solving task and never applied herself to it again as a neurosis, because it was "relatively

permanent." Galt (1939) found a similar change in behaviour lasting two months in a *cebus* monkey after it had been presented with an especially difficult discrimination problem, and Firsov (1952, in Liberson, 1957) reports that during operant conditioning (squeezing a bulb) to visual and auditory signals in monkeys, one broke down and became neurotic for a month when discrimination of signals was required.

Apparently spontaneous cases of neurosis in primates are also reported. Leavitt and Riggs (1942) recount the case of a young monkey who exhibited a "change of personality" after living for two and a half years with a policeman, but better authenticated are Hebb's cases of two adult chimpanzees who both showed disturbed behaviour not traceable to any discoverable trauma (1947). The first had been reared in the laboratory since birth, the second since nine months of age, so that their histories are well documented. The first showed a recurrent food phobia, occasionally associated with fear of an attendant; the second, recurrent fits of depression. In neither case was it possible to find any specific experiential cause. For example, Hebb examines and rejects the possibility that a hurtful object may have occasioned the food phobia. He considers that the disorders mentioned meet all the criteria he has laid down for animal neurosis, "as far as this can ever be possible in the absence of the verbal examination of the patient" (1947, p. 11). An apparently spontaneous case of gross self-mutilation which appears to have been associated with depression and the relationship with an attendant, is reported by Tinkelpaugh (1928), but the possibility of chronic disseminated encephalitis must be suspected in such cases (Hutyrá, Marek and Manninger, 1946). Apparently abnormal motor behaviour in caged wild animals, such as stereotyped pacing movements, may be attributed (Hediger, 1950) to the interaction of the shape and size of the cage and the animal's "flight distance." Little appears to be known about abnormal behaviour in wild animals in their natural state. The apparently purposeless mass migrations occasionally reported are probably the result of ecological factors.

Later Studies, especially on the Rat

Turning to the last major section of work to be included in this review, we encounter a somewhat more rigorous methodological climate. This is perhaps because the investigators were usually trained psychologists, and frequently worked with the rat as subject. The early work of Liddell and Gantt aroused interest in the topic of experimental neuroses in the late 1930s, as may be seen by the numerous reviews of the field which appeared (Murray, 1937; Miles, 1938; Cook, 1939, 1939a; Witkin, 1939; Karn, 1940, 1940a). Interested workers tried to study the

phenomena described by using the standard laboratory animal, the rat. Advantage lay in the greater accessibility and convenience of this subject over the more esoteric species previously used, and the possibility of using larger numbers was also clearly attractive, thus avoiding the defects of lack of control and of statistical criteria, which it has been unfortunately necessary to stress time and again in this chapter. There seem to be two reasons, however, why research along these lines did not develop. Firstly, the problem proved intractable, as, looking back on it, one might have expected in view of the nature of the evidence produced. Secondly, the investigation of audiogenic seizures claimed the attention of many workers. Effort was needed to establish that the convulsive phenomena observed were not rodent parallels of the classical experimental neurosis, and they were thereafter studied for their own interest. The more basic research on the rat has never been resumed on the same scale. After reading this chapter, it may be conceded that this, perhaps, is not a bad thing.

This is not to say that early references to experimental neurosis in rats are not to be found. Some writers identify any slight deviation from what they consider to be normal performance as "neurotic" (Fields, 1931; Hall, 1933; Carmichael, 1938),¹ though others are more restrained (Miller and Stevenson, 1936; Sampson and Schneirla, 1941). However: "During the period from 1937 to 1940 there was a rather widespread effort to establish experimental neuroses in the rat with conflict as the precipitating factor. Very few of the published studies reported success, however, and it is reasonable to assume that many failures never reached print" (Finger, 1944, p. 413). Among those reported, Cook's are notable for his thoughtful analysis of the problems involved (1939, 1939a) and his painstaking attempts to overcome them (1939b). Defining experimental neurosis in terms involving Hebb's criteria of chronicity, evaluational abnormality and departure from a previous base-line, he reviews the literature to date and identifies four major factors common to the situations yielding experimental neurosis. They are the use of restraint, the development of learned responses by Pavlovian conditioning, the discrimination of similar stimuli giving rise to antagonistic responses, and the inhibition of responses during excitatory stimulation. In preliminary work he used three situations in which the first two of these elements were lacking before turning to a method of conditioning in the rat, developed by Schlosberg and his associates (1934, 1934a, 1934b, 1936, 1936a; Schlosberg and Kappauf, 1935; Kappauf and Schlosberg, 1937; Hughes and Schlosberg, 1938).

¹ This tendency persists; examples range from cattle (Fraser, 1957), through rodents (Green, 1958; Hansen, 1956), to the amoeba (Goldacre, 1958)!

The rat is immobilized by strapping it down in a miniature harness to a stand, and attaching an electrode to one foreleg, the withdrawal of which is automatically recorded. Cook's technique was to associate foreleg retraction first to the appearance of food in a cup near the rat's head, then to limit the movement's effectiveness in producing the food reward to the period when a bright light—the positive conditioned stimulus—shone. Next came training to inhibit the foreleg response in the presence of a dim light—the negative stimulus—by punishing such responses with shock, before the intensity of this light was increased to make the discrimination more difficult. All the six rats put through this procedure showed their dislike of it by squealing, tenseness, etc., and there were transient disturbances of the learned response, but only three rats showed some other change in behaviour such as avoiding being handled by the experimenter or becoming unresponsive to stimuli—changes which Cook thinks meet his definition of experimental neurosis: "chronic, abnormal behaviour, experimentally produced." He notes that the effectiveness of the situation involving restraint supports Liddell's view on the importance of this factor in the aetiology of experimental neurosis.

An even more thoroughgoing attempt to adapt the Pavlovian conditioning procedure to the study of experimental neurosis in the rat is due to Bijou (1942, 1943, 1947, 1951). In preliminary work (1942) he found that quicker learning was achieved by using head movement rather than leg retraction, and greater discrimination by varying the position of the stimulus lights rather than the brightness of a single panel. In a further study of eight rats differential conditioning was developed, after many trials, in five of them to the point where they were discriminating lights about one inch apart. Activity, measured before each training session, the degree of restraint used, and the subjects' emotionality, defined by defecation scores in Hall's open-field test (1934), were apparently unrelated to the speed of learning, but the use of shock to punish wrong responses "markedly increased excitable behavior." No abnormalities other than this latter were found. Later modifications to this apparatus and procedure (Bijou, 1951) and work using it to investigate other aspects of learning (Rohrer, 1947; Rigby, 1954) have been published without further attempts to precipitate experimental neurosis.

Using a more strictly Pavlovian procedure, but still employing movement as the response to be conditioned, Kawamura and Yoshii (1951) restrained thirty-six rats in a cloth holder (Cowles and Pennington, 1943) and applied an electric shock to the hind leg, preceded by an acoustic stimulus. In the absence of quantitative data it is not clear how the conditioning

developed. Tremors and tics of the hind legs are reported in five subjects, trained over two months, as well as resistance to being placed in the conditioning box and hypersensitivity to stimuli in their home cages. It is not, of course, possible to agree with the authors' identification of such behaviour as experimental neurosis, nor is their definition of phases of rats' behaviour involving hyperactivity as "acute experimental neurosis" helpful. Their use of stimulant and depressant drugs, of surgical intervention including prefrontal leucotomy, and of electroencephalography is of greater interest. Only the last is reported in any detail: Yoshii and Kawamura (1951) implanted electrodes in five rats. No abnormal wave forms were observed, and, though there is some evidence that two "neurotic" rats showed faster waves, the absence of normative data does not permit firm conclusions.

Another attempt to use Pavlovian conditioning techniques in the rat arose out of the report (Jamison, 1951) of the conditioning of a heart rate decrement which reflexly follows the inhalation of ammonia gas. A preliminary report (Broadhurst, 1954) failed to confirm the existence of this conditioned response, though a small, albeit statistically significant, conditioned cardiac response based on shock, rather than on ammonia gas, as the unconditioned stimulus was found, as well as unstable squeak and respiratory conditioning also based on the shock. No responses, however, were sufficiently definite to form the basis for differential conditioning.

It may, therefore, be said that the application of conditioning methods to the rat for the production of experimental neurosis has failed in its object. Not only have there been no reports of disturbances comparable to those reported with the use of higher animals, but the conditioning technique itself has not produced unequivocal results. It has proved just as time-consuming as with higher animals, thus frustrating the aim of employing large numbers of cheap and readily available subjects for control and statistical purposes. It is not surprising that other methods have been frequently tried.

Hunt and Schlosberg (1950) belatedly report work done in 1938–40 on the use of a "continuous conflict" situation. Of ten rats kept in stabilimeter cages to record activity, six had their water supply electrified so that every time they took a drink they received a shock from the nozzle of the water bottle, and the other four served as controls. The data presented on activity suggest that the experimental animals became more active throughout the whole day, instead of sleeping principally during the day and becoming livelier at night—the rat being a nocturnal animal: "The writers interpreted this difference to mean that continued thirst kept the animals active during the normal hours of diminished activity but did not

increase the total amount of time spent in resting or sleep. Since these relatively meager results seemed to have little to do with conflict, *per se*, no further study was made of general activity" (1950, p. 150). This view reflects the search for the overt signs of abnormal behaviour in animals, which are probably not to be found. It is especially unfortunate in this case, since this same finding of increased activity during the animal's "night" is one of the few reported in other species, as mentioned in discussing the Cornell work on sheep, where thirst could not be invoked as an explanation. Hunt and Schlosberg, however, are more impressed by some incidental observations. Rats bit the nozzle of an unelectrified water bottle, apparently trying to get it into the cage, they would suddenly cease drinking from it as if shocked, and finally showed "tantrums" in which they threw food about and breathed noisily. But the latter behaviour may be observed in naïve rats never subjected to experimentation, and water-deprived ones will display the apparently aggressive behaviour towards a water nozzle with no experience of shock whatsoever. Finally, the "hallucinatory" behaviour towards the previously electrified spout may be the result of a conditioned anxiety response to it.

Only Finger (1941) appears to have taken up the suggestive findings relating to changes in activity. In a carefully controlled study, he measured general cage activity during an extended period while the subjects were also exposed to difficult discrimination problems in a Lashley jumping stand. He found a significant decrease in activity in the twenty-four-hour period following jumping sessions in which four or more errors had been made, as well as a significant increase during the following day—the rats' night. Non-jumping controls showed no change. To what extent these changes are attributable to the conflict caused by the difficult discriminations is not clear since an alternative possibility, that the incorrect jumpers were simply more tired than the others, and so slept more during the next rodent "day," is not excluded. Some data showing that the effect dissipates within twenty-four hours are not inconsistent with this explanation, though others militate against it.

King and Mavromatis (1956) used Hunt and Schlosberg's technique to study the disruptive effect on the re-learning of a conditioned avoidance response to shock of intermittently electrifying the water supply of two strains of mice. While there was a significant decrement in saving scores, as compared with appropriate control groups, the authors rightly conclude: "... it is impossible to assign this interference to emotional 'disturbance' experienced by the mice in the conflict situation or to a physiological adaptation to shock" (1956, p. 468). The further use of the continuous conflict technique in the production of gastro-

intestinal disorders in animals will be noted later. Cook's use of it (1939b) in his search for a method of producing abnormal behaviour in the rat yielded no positive findings; neither did his use of a Miller-Mowrer type shuttle box in which the rats had to learn a brightness discrimination to avoid shock. Gentry and Dunlap (1942), however, forced the rat to escape from a strong shock only to meet a weak one. None of these workers found disturbed behaviour, though Gentry and Dunlap claim to have shown "atypical" learning among their twelve subjects after exposure to the shock situation and Eränkő and Muittari (1957) report changes in thyroid structure as a result of extinguishing a jumping response.

An apparatus designed to enforce wakefulness in rats might be thought provocative of disordered behaviour. Licklider and Bunch (1946) kept each subject in a cell, the floor of which was a roller surrounded by water. For control groups, the roller was locked stationary, whereas for experimental groups it was free moving, thus forming a treadmill on which animals had to move every ten to fifteen seconds in order to avoid falling off into the water. While the sleepless animals which survived became highly irritable and aggressive by the thirtieth day, no more profound disorders were reported. This was also the case in a report of enforced lack of sleep in dogs (Okazaki, 1925).

Humphrey and Marcuse's (1939, 1941) claim to have produced "neurotic behaviour" in rats by dragging the bottomless goal box of a maze across the floor after the rat had entered it cannot be entertained seriously, if only because the behaviour in question consisted principally in hesitation in entering the same goal box on subsequent trials. A very different situation has been reported to produce "psychotic" behaviour in wild rats. During toxicity tests, Richter (1950) found that wild Norway rats developed "refusal" responses after a sublethal dose of one poison, ANTU (alpha-naphthyl thiourea), presumably because they had associated its taste and smell with the respiratory distress caused. Typically, Richter used two food cups and switched the poison from one to the other. Just after this had been done, one animal developed a pseudo-catatonia, maintaining an awkward posture on its hind feet despite interruptions including the opening of the cage. This is most unusual for wild rats, which are always eager to escape. This "straphanging" behaviour lasted for two months before the rat was finally poisoned. Other rats showed similar behaviour which Richter interprets as "an ever-present fear of being poisoned." But this promising lead has petered out, as further work on over a hundred subjects has proved negative (Richter, 1953), and it is now thought that the upright posture may have resulted from the earlier experience of

huddling closely when many were confined together in one cage. Moreover, wild rats sometimes show their intense fearfulness after capture by remaining motionless, even starving to death in the process, by dying of fright when handled, as Richter himself has shown (1957), or when fighting, even when uninjured (Barnett, 1955). The domesticated rats in Richter's experiments never showed comparable behaviour, and this fact alone robs the original finding of its relevance in the present connexion, since the wild rat, which needs special techniques in handling and testing (Broadhurst, 1958*a*), cannot be regarded as a standard laboratory animal. At this point the reader may be disposed to agree with Hebb's comment of over ten years ago: "I have seen nothing in the literature which remotely justifies calling rat behaviour neurotic" (1947, p. 14).

While examples of abnormal behaviour in animals other than the rat, or as a result of using techniques other than those discussed are worthy of mention, none of them approach the definition of neurosis adopted here. Karn (1938, 1938*a*; Karn and Malamud, 1939) used the double-alternation problem in a temporal maze. This is a difficult problem, the animal being required to go through the same passages of a rectangular maze four times, making different turns on the last two trials from those made on the first two. Two cases of behaviour disturbance are reported, one in a cat and one in a dog. Another animal of each species was not affected. In each case the affected animal halted at the choice-point, and cried; the cat showed a reluctance to enter the maze. Both animals failed to reach their previous performance, which fact in particular led Karn to describe the behaviour as "neurotic." However, subsequent workers using this type of problem with a larger number of cats specifically note the absence of behaviour comparable to that reported by Karn (Willoughby and Andrews, 1940; Stewart and Warren, 1957).

Cameron (1936) encased the rear legs of eighteen guinea pigs hoping to produce experimental depression by frustration of movement. This treatment did reduce the rate of respiration, but since it caused physical damage to the legs in almost all cases, the finding is on these grounds alone uninterpretable.

Despite the widespread use of birds as experimental animals, and their tendency to "superstitious behaviour" (Skinner, 1948; Morse and Skinner, 1957), there are few reports of abnormal behaviour among them. Bajandurov (1933) developed a Pavlovian conditioning procedure in doves that were restrained in a holder with an electrode attached to one foot. The response of the leg to a shock was recorded by an attached thread, and was conditioned to the appearance of illuminated shapes before the bird. The classic method of developing a positive response to a circle,

a negative one to an ellipse, and then making the ellipse progressively more circular, had the expected result. The discrimination broke down, and the previously quiet bird struggled against the restraint. A second subject became agitated with interval activity of the reaction limb, though retaining the discrimination. Brückner (1933) induced disordered behaviour in four hens by isolating them in a closed box for the first seven weeks of life. On restoration to the flock, two of them were distinguishable by their unusual behaviour for three days in one case and twelve in another. But the deprivation of visual stimulation during what probably was a "critical period" of development (*see* Thorpe, 1956) may be at least as important a factor as the isolation. Many studies (*see* Beach and Jaynes' review, 1954) indicate the importance of the effect of early experience on adult behaviour. Examples of observational accounts of abnormal behaviour in birds are Lorenz's description (1940) of depression in a grey goose after one wing was clipped, and Räber's report (1948) of the abnormal development of courting behaviour in a turkey. It would display before a mackintosh hanging on a post, which it never did before a hen bird.

These contributions have clearly not advanced a solution of the problems raised by experimental neurosis as reported by early workers. The problem has indeed proved intractable so long as it continued to be posed in terms demanding a solution by the production of overt abnormalities which would serve as convincing analogies of those seen in human neurosis, and so long as human neurosis itself continued to be regarded as a discrete disease entity, instead of the extreme of a continuum of learned, and probably overgeneralized, responses, some of which are in fact amenable to rational therapy based on learning theory (Wolpe, 1952, 1952*a*, 1958; Jones, 1956; Yates, 1958). This view, developed elsewhere in this book,¹ makes the study of disorders of emotional responses in animals by approaches other than that of experimental neurosis directly relevant to human problems. This is particularly true if the view is taken that cross-species identification of behaviour is permissible when it can be shown that the mechanisms giving rise to the behaviour are the same in the two cases. No attempt is made here to review all the pertinent literature, but mention of some papers will indicate the range of the possible approaches.

An interesting early attempt by Higginson (1930) sought to quantify the effect of emotional stress—a naturalistic one, the fear of cats (Curti, 1935)—on a series of measures of rats' performance in a maze. Turner (1941) amplified this approach by observing the effect of a difficult size discrimination on rats' behaviour in other situations. He confirmed Finger's

¹ *See* Chapters 1, by H. J. Eysenck and 20, by H. G. Jones

finding (1941) of a depression in activity and showed a similar effect on respiration, with no effect on startle responses. Scott (1947; Scott and Marston, 1953) has also used a naturalistic stress—in this case defeats in fights—to study emotional behaviour in mice. McCleary (1954) gives a good-humoured account of a quest for cardiac measures of stress in rats. After solving the not inconsiderable difficulties associated with obtaining such records from a freely moving animal, thus avoiding the objections, both practical and theoretical (*see* page 737), to attaching electrodes, he succeeded in getting clear records of increase in heart rate when the rat heard a tone associated with shock. But control tests showed a similar increase in simple movements which apparently involved no anxiety. He doubts the value of cardiac measures of anxiety: “Maybe one would rather conclude that the rat is simply ‘anxious’ about everything he does. It’s a moot point. Operationally, one ends up at the same place” (1954, p. 107).

The approach-avoidance model of behaviour developed by Miller (1944, 1951) offers a fruitful approach to the study of conflict between tendencies. An example is Winnick’s success (1956) in giving quantitative expression to the fluctuations in anxiety, postulated as occurring in such conflict situations (Schoenfeld, 1950). She recorded the intensity with which hungry rats pushed against a panel, the release of which in order to feed would switch on a bright light—an aversive stimulus. The measurement in a readily quantified form of the conditioned emotional response or C.E.R., referred to earlier as the probable basis for feeding inhibitions, has given rise to a number of studies in which the effect on it of other variables has been examined (*see* Brady and Hunt, 1955; Brady, 1957). Another, somewhat more direct, measure of autonomic arousal in the rat—the defecation score in Hall’s open-field test (1934)—has been used in the analysis of the determinants of emotionality (Broadhurst, 1957, 1958, 1958*a*) as well as providing the basis for the investigation of inherited emotional characteristics (1959*a*, 1960) and of their effect on learning (1957*a*, 1957*b*, 1958*b*). This work suggests that emotionality may be a rodent analogue of neuroticism in humans; the analogue of the orthogonal dimension of introversion-extraversion has also been tentatively identified (Sinha, Franks and Broadhurst, 1958). Factor analysis is another promising approach (Royce, 1950). Examples are seen in Royce’s work on the dog (1955), Sen’s on the rat (1953) and Willingham’s on the mouse (1956).

The effect of psychological stress on physiological function, as seen in Pilgrim and Patton’s study (1953) of growth in rats, which yielded negative results, and Ullman’s (1951, 1952) on “compulsive eating,” which was positive, has received new impetus with the report

of the experimental production of gastric ulcers in the rat by Sawrey and Weisz (1956). A continuous-conflict technique like that used by Hunt and Schlosberg opposed severe hunger and thirst drives against fear induced by shock as the animals tried to approach food or water. Both authors have published apparently independent analyses of the variables involved (Sawrey Conger and Turrell, 1956; Weisz, 1957) which agree in assigning an important role in ulcer formation to the conflict involved, as opposed to the effect of shock or of deprivation alone. No overt behavioural changes were observed. The influence of some social factors has been demonstrated (Conger, Sawrey and Turrell, 1958), and other work showing that ulceration may be induced by direct brain stimulation (French, Porter, Cavanaugh and Longmire, 1957) suggests the possibility of identification of the cerebral mechanism involved, especially in view of the extension of the technique to primates (Porter, Brady, Conrad, Mason, Galambos and Rioch, 1958).

The approach of comparative ethologists¹ to the problems of abnormal behaviour is based on their concept of “displacement activity,” the manifestation of an innate behaviour pattern in circumstances which are judged biologically inappropriate for its emergence (Tinbergen, 1952; Barnett, 1955*a*). Careful analysis of the determinants of such behaviour have been made (*see* Thorpe, 1956). Displacement activities are viewed as the basis of the phenomena of experimental neurosis (Bastock, Morris and Moynihan, 1953), as well as being related to those seen in human neurosis (Armstrong, 1950) especially psychosomatic disorders, which Barnett (1955*a*) suggests may be analogous to displacement activities in lower animals. The difficulty that the responses in lower animals are usually motor ones, whereas in man they tend, especially when pathological, to be visceral, is now less cogent in view of the work on gastric ulcers mentioned above and the development of methods for the study of asthma in lower animals (Ottenberg, Stein, Lewis, and Hamilton, 1958).

This, then, concludes the review of the factual evidence which is to be found in the experimental literature and which goes to make up our knowledge about experimental neurosis. As has been indicated, there seems very little justification for the view that

¹ Many ethological concepts can be criticized on various scores (Schneirla, 1952; Kennedy, 1954), and the ethologists’ models may repel those accustomed to the greater sophistication of modern learning theory, which covers part of the same ground: “The gulfs between psychiatry, psychology, ethology, and physiology are both deep and wide, and the attempt to bridge them is liable to bring on fits of dizziness” (Barnett, 1955*a*, p. 1207). Such attempts are not encouraged by some ethologists’ definition of their area of work as the scientific study of behaviour, thus pre-empting a field long studied by psychologists, the relevant contributions of whom many ethologists in their writings, though with certain significant exceptions, e.g. Thorpe (1956), appear to ignore.

the phenomena observed can, in all but a very few cases, be regarded as at all analogous to the phenomena observable in human neurosis. Nevertheless, it has frequently been accepted that they are so related, probably because of the lack of a theoretical framework which links them to the main body of findings in the field of animal studies. This reinforces the view, as Lichtenstein has noted (1950), that one is dealing with examples of behaviour which are strange, and thus "abnormal": it is then but a short step to defining them as "neurotic."

Theoretical Formulations of Experimental Neurosis

Two attempts have been made to describe the disturbances of behaviour experimentally produced in terms of a coherent theoretical system. These are the "vigilance" theory of Liddell, and Gantt's principles of "auto-" and "schizokinesis." Both of them, however, are *sui generis*, in that they account only for the facts of experimental neurosis as observed by their authors, and there has been very little success in demonstrating that they have any relevance beyond the situation which they were designed to illuminate. Moreover, as has been indicated in discussing them, they are not couched in terms sufficiently precise to allow testable predictions to be made from them.

To achieve the desired theoretical integration in this field, then, it seems necessary to go back to the originator of the area of study. Pavlov viewed experimental neurosis as behaviour resulting from a "clash" between cortical excitation and inhibition. This explanation in terms of a theory of brain physiology which is not widely accepted by physiologists (Liddell, 1949) in fact adds little to our understanding of the nature of the behaviour involved, and it is natural that, in seeking to encompass the problem, recourse should be had to the modern successor to Pavlovian reflex theory, that is the learning theory of Hull whose debt to Pavlov is insufficiently recognized. While recognizing the system's imperfections, it seems true to say that many, perhaps a majority, of psychologists, would acknowledge that learning theory as developed by Hull and elaborated by his pupil, Spence, and by Mowrer, Miller, and Eysenck, is at present the only coherent and consistent explanation of numerous widely differing phenomena which range from the behaviour of *paramecia* (Grosslight and Tickner, 1953) to the development of social attitudes (Eysenck, 1954). Two attempts within this general framework may be noted. Hebb's (1947) is in the nature of a series of general suggestions which might adumbrate a fuller treatment. For example, he stresses the importance of generalization in the development of disturbed behaviour outside the precipitating situation, and regards the emotional responses displayed within it as being the result of "normal emotional

conditioning." A more elaborate attempt is that of Wolpe (1952); indeed, Wolpe's whole thesis is that experimental neuroses are in fact learned behaviour, irrespective of whether one regards them as abnormal or not. To this end, he categorizes the precipitating situations into those employing severe shock, those employing mild shock, and those employing ambivalent stimulation. The behaviour resulting from the first he regards as straightforward fear conditioning in which the stimuli associated with the punishing shock become conditioned stimuli for the arousal of intense conditioned fear, that is, anxiety. With regard to the second situation in which mild shock only is used, "it is necessary to explain how a severe anxiety reaction could arise from what is apparently nothing more than the repeated conditioning of a mildly disturbing stimulus" (Wolpe, 1952, p. 265). His solution is to postulate that fear and anxiety have additive properties. To the slight amount of fear evoked by the conditioned stimulus, must be added the even smaller anxiety conditioned to it by the previous occasion on which it was used. This, however, allows a slightly larger amount of the complex of fear and anxiety to be conditioned to the stimulus, which, in turn, means a greater amount of anxiety to be added to the fear on the next occasion—and so it goes on. In this way, Wolpe suggests, anxiety can mount, so that, in time, the responses to it overwhelm other learned behaviour. With respect to the third situation, that of ambiguous stimulation, Wolpe offers this hypothesis—

However slight and transient the anxiety produced by this conflict of tendencies may be at first, the drive reduction associated with its cessation results in the anxiety responses becoming reinforced to whatever stimuli are contiguous, and among these is the ambivalent stimulation itself. In the same way as suggested above for the case of mild noxious stimuli, the strength of the anxiety response is conceived to be gradually stepped up at each presentation of the ambivalent stimulus situation while the drive-reduction potential correspondingly grows. Eventually very powerful anxiety responses are evoked, and strong avoidance behaviour entirely replaces the approach responses to the experimental situation which were previously established by repeated feeding (1952, p. 266).

Thus, two authorities appear to support the view taken earlier in this chapter that the responses observed in the situations in which strong shock or other noxious stimuli are used (e.g. Masserman's) may be subsumed under the category of conditioned emotional responses. Hebb also appears to think that all phenomena of experimental neurosis can be so explained. Significantly, the only exception he apparently makes is the phenomenon of diminished capacity for making simple discriminations of

conditioned stimuli after the application of difficult ones has caused a breakdown. It is this latter situation also which causes Wolpe most difficulty. To be sure, it is easy to see that once intense anxiety has been produced in the difficult discrimination situation, a conditioned emotional response to the stimuli used, and to the whole situation, will develop and generalize in the usual way. What is more difficult to see, is how this anxiety developed in the first place, in the absence of primary fear-producing stimuli. Wolpe's explanation, though ingenious, does not appear to the writer to be wholly satisfactory. Firstly, his assumption that fear and anxiety are additive may not be tenable. Secondly, that they do interact in the way suggested is equally hypothetical. Thirdly, even if these points are conceded, then in the discrimination situation, his explanation rests on the assumption that ambiguous stimulation gives rise to anxiety, directly. He claims that: "... it is a matter of everyday experience that in human subjects ambivalent stimuli arouse feelings of tension" (Wolpe, 1952, p. 266). Admittedly, there is a body of evidence which suggests that this may be in fact true, but Wolpe does not indicate how this occurs in animals. An explanation in terms of changes in difficulty level may be of assistance here; such an explanation is available in terms of the operation of the principle known as the Yerkes-Dodson law.

In 1908 Yerkes and Dodson published the results of a study of learning in mice in a brightness discrimination situation. They found that as the motivation—in this case a combination of hunger drive and electric shock punishment for wrong responses—increased, an optimum motivation was reached beyond which increases in intensity gave poorer rather than better learning. But in addition they investigated the effect of variations in the *difficulty* of the task. They discovered that the more difficult the task, the sooner the optimum motivation was reached, that is, as task difficulty increases, so the optimum motivation approaches threshold. The curvilinear relationship between performance and motivation has been confirmed in many different situations subsequently, but the relationship between it and the level of difficulty appears to have been lost sight of until recently, when the law was invoked (Eysenck, 1955) to explain the differences in performance between neurotics and normals in their accomplishment of simple tasks like conditioning, and more complex ones like maze learning (Taylor, 1956). Broadhurst (1957a) has demonstrated the action of the law itself in a factorial experiment in which it appeared as a significant interaction effect between intensity of motivation and level of task difficulty. This confirmation is thought to gain weight because a different situation, different motivation, and even a different species of subjects

from those of Yerkes and Dodson (1908) were used. In addition, the phenomena designated by the law may be explained in terms of Hullian learning theory. Thus, increasing drive level may increase the functional difficulty of a discrimination, so that objective increases in difficulty are in fact rendered more severe than the circumstances otherwise warrant. Once the optimum motivation is reached, then the decrease in task performance may be viewed as an energization of incorrect responses which are lower in the habit-family-hierarchy than the correct ones (Broadhurst, 1959). The application of this reformulation of the Yerkes-Dodson law has been shown to have relevance to such diverse fields as perceptual defence and avoidance learning, as well as experimental neuroses. (See Chapters 7, by J. Inglis and 13, by H. G. Jones.)

The application to the problem of how to account for the disturbed behaviour seen in experimental neurosis precipitated by difficult discriminations derives from the nature of the task imposed in this type of situation. After preliminary training in restraint, during which time the subject's fear reactions to the restraint and to the experimental situation generally are gradually inhibited and replaced by food seeking responses, the task proper begins. A feature of it is that the task becomes progressively more and more difficult—as soon as the animal masters one discrimination a start is made on the next and so on. Now, from a consideration of the action of the Yerkes-Dodson law, it is clear that the optimum performance will be achieved by the subject in this situation with a progressive *lowering* of motivation. That is to say, the optimum motivation for each new level of difficulty will be lower than that for the preceding, easier one. But it seems unlikely that experimental animals will have encountered situations before in which this principle operates, that is, in which greater reinforcement follows lower rather than higher motivation, and so will not have had the opportunity for learning which particular level of motivation will secure a desired goal. On the contrary, most of the situations they are likely to have encountered previously are simple ones in which higher drive levels have in general been more efficacious than lower ones. It is postulated, therefore, that the result of failure in the discrimination situation to receive the anticipated reinforcement when the subject responds wrongly to a negative conditioned stimulus will result in an increase of motivation, by virtue of the previously learned responses referred to above. Subjectively speaking, the natural result of failure is to try harder. Thus a conditioned increase of drive (Brown and Farber, 1951; Marx, 1956) may be added to that already existing. This, in turn, will lead to further failure to make the discrimination, and additional slight increments in drive may be expected

because of the added delay in anticipated reinforcement which may occur, and because of the drive arousal cues now associated with both positive and negative stimuli, which, typically, are now both responded to equally. At this stage, it is further suggested, the increased drive level energizes incorrect responses in competition with the correct ones—responses, especially fear ones, which were suppressed early on in the training. So it is that struggling, howling, and agitated behaviour in general, which were previously characteristic of the subject's initial reactions to the situation are reinstated anew.

This formulation serves to reconcile certain phenomena frequently reported in conditioning work which do not seem to have been adequately explained hitherto. Several experimenters have mentioned the failure of the method of improving the subject's discrimination performance by increasing the hunger drive: if the above analysis is correct, the prediction might be made that reducing the hunger drive, rather than increasing it, would be more beneficial. In the same way, the observation of some workers that making the discrimination problem simpler has therapeutic value fits in with our formulation. On the other hand, the more common finding is that after the breakdown of discrimination at extreme levels of difficulty, even simple discriminations are no longer made and have to be re-learned. It seems probable that this characteristic failure of simple discrimination can be accounted for if it is recalled that even relatively simple tasks have an optimum motivation, which may well be surpassed if anxiety is added to the motivational complex.

One ubiquitous finding—Pavlov and Gantt, as well as Liddell and Masserman all mention it—is that the presence of the experimenter in the conditioning chamber with the subject appears to have a quieting effect on neurotic animals. Anderson and Liddell (1935) came nearest to a rational explanation of this fact when they observed that conditioned signals are not given when the experimenter is in the room. Now, the task this poses the animal is to distinguish between "experimenter present" and "experimenter absent"—an extremely simple perceptual discrimination. The simplicity of this task is such that it seems likely that it will be very well learned, even under the extremely high drive postulated as eventuating from the previous breakdown. Also this high drive level may be responsible for the rapid learning of any other novel feature in the experimental situation, especially if it has any drive reducing properties. Herein may lie the clue to the so-called pathological generalization of the disorder of Gantt's dog "Nick," who, it will be recalled, developed genito-urinary signs long after the original precipitating cause of the experimental neurosis had passed. They did not, however, arise spontaneously.

They followed the introduction of a bitch in oestrus into the experimental situation for therapeutic purposes. It is suggested that the pollakiuria and sexual erections noted in this dog thereafter may in fact have been conditioned responses to the experimental situation, the female acting as the original unconditioned stimulus. It should be noted that the transient abnormalities of sexual function noted in another dog (Gantt, 1944) followed attempts to develop sexual conditioned responses in the experimental situation. Two further facts about "Nick" seem to support our view; the dog learned a new association to light as a conditioned stimulus without any reward, which suggests a continuing high drive level; as does the observation that he persisted in looking towards the location of the original auditory conditioned stimulus, many years after it had been altered.

While this attempt to account for some of the facts of experimental neurosis in learning theory terms is doubtless deficient in many respects, it serves to indicate that it is likely that the phenomena observed can be brought under the rubric of conventional learning theory in a general way. More can hardly be expected at this time in view of the deficiencies in the evidence available. Significant advance in the future probably lies in the use of more strictly controlled situations for the study of the development of emotional responses—the conditioned emotional response (C.E.R.), for example—which permit detailed analysis of the stimuli and responses involved, such as that, for example, of Schoenfeld (1950). He writes: "The distance from rat to man is a long one, yet it may turn out to be filled with differences in detail rather than in principle. Most, or all, experimental psychologists are as vitally interested as the clinician in understanding man, but use the laboratory as their route to that goal in the belief that through it may be achieved a sound theory of behavior leading to widened practical successes in the field" (1950, p. 95).

CHAPTER 20

Applied Abnormal Psychology: the Experimental Approach

H. GWYNNE JONES

INTRODUCTION

THIS chapter, unlike those preceding, does not include a review of literature but merely expresses a point of view concerning the practice of clinical psychology and based on a particular conception of the role of a psychologist in a psychiatric institution. This point of view is not peculiar to, nor was it originated by the writer. In general, it is shared by his colleagues of the Psychology Department at the University of London Institute of Psychiatry and has been advocated in earlier papers by Shapiro (1951, 1957), and also by Eysenck (1952, 1955) and Payne (1953, 1957). The section on treatment, for which the writer assumes a greater measure of personal responsibility, is largely based on two previous papers (Jones, 1956*a*, 1958). Each single aspect described has figured in the writings of psychologists from many clinics but a consistent application of this general approach seems rare in practice.

The aim and concern of the clinical psychologist, like that of the physician, social worker, or nurse, is to foster the welfare of individual patients. In order to justify his separate professional existence, he must, by virtue of his particular qualifications, make some independent contribution to the furtherance of this aim. Moreover, in so far as he insists on professional status, this contribution should be at a responsible level and he bears the onus not only of practising but of developing his techniques. (Despite the varying content of courses of training in clinical psychology, graduate status in academic psychology is a universal pre-training requirement.) Thus, it seems clear that the special contribution of the psychologist should be the application of the findings and techniques of general psychology to the problems involved in the investigation and treatment of psychiatric patients.

This might seem a statement of the obvious but, in practice, many factors influence the psychologist into accepting other roles. Not least among these is the

low status of psychology as a scientific discipline, both in terms of its reputation among representatives of other disciplines and in terms of actual achievement as represented by a coherent body of knowledge, codified in terms of clearly defined concepts and laws concerning the interrelationships between these concepts, which have been verified empirically and are generally accepted as valid. As a consequence of this lack of status, psychology, as taught academically, does not bear the same fundamental relationship to psychiatry as, for example, physiology bears to physical medicine. Faced with the problems of treating dysfunctions of behaviour, psychiatrists have evolved their own "psychologies" to explain behaviour and, despite deficiencies at least as serious as those appertaining to academic psychology, these tend to acquire the status granted to medicine in general.)

In these circumstances, it is not surprising if a psychologist entering a clinic is less confident than a biochemist or physiologist that he has a science to apply and seeks other means of justifying his employment. Mental hospitals and similar institutions are frequently under-staffed and the needs of patients are many. Occasionally a psychologist of humane outlook makes a major contribution in such a setting by virtue of his personal qualities rather than his psychological training; a contribution which, given equal opportunity and equal calibre, could be made equally well by a social worker, minister of religion, or intelligent layman with some experience of mental disorder. Others take over the concepts and methods of psychiatry and become assistant psychiatrists, but with some special knowledge of certain test procedures, which derive from psychiatric theory, and which are validated against psychiatric opinion and are administered routinely or by specific request.

The deficiencies of psychology as a science are not,

however, so great as to render its application impossible or even inadvisable. Though thoroughly validated theories embracing broad aspects of behaviour are lacking, there are many more satisfactory miniature theoretical systems and empirical generalizations concerning a wide range of phenomena. Even in the restricted field of abnormal psychology, there are sufficient data to have enforced a handbook of this magnitude, though much that would be apt to discussions of many psychiatric problems has been omitted. The more speculative broad theories are also of value if they are testable in the sense that they mediate predictions which can be subjected to empirical verification. This does not necessarily imply that a simple direct test of a single unequivocal prediction can be made. The more complex a theory the greater its susceptibility of disproof, in that it generates predictions over a wider range of phenomena, but each single prediction refers to more variables, which may then exceed the possibilities of control in a single experiment. Application in the clinical field may serve as a complex test of a complex theory, leading to refinement of the theory and improvement of clinical techniques.

Apart from its *content*, general psychology may contribute much in terms of *method*. The use of standardized validated test procedures, derived from differential psychology, is common in clinical practice but far less use is made of experimental techniques though, for many purposes, their utility is immensely greater. Thus an individual may present or complain of an apparent psychological abnormality for which no general explanation is available. Whether or not similar abnormalities are displayed by other individuals, this may be investigated as a miniature research problem in its own right. First the abnormality is described in terms of the concepts of general psychology by eliciting and observing relevant behaviour in a standard controlled situation. This observation is objectively recorded and, ideally, takes the form of quantitative measurement. Hypotheses are then formulated concerning more basic factors and processes contributing to the abnormality and predictions from these tested experimentally. If, during this procedure, independent variables are discovered which enable the psychologist to bring the abnormality under experimental control, therapeutic procedures may be devised around these variables.

In many such investigations no external control data are necessary as the predictions tested are concerned entirely with variations in the subject's performance from situation to situation. Provided that the experimental design allows for the effects of such factors as practice, the subject may then be used as his own control. Maxwell (1958) discusses at length many such experimental designs and various

statistical procedures applicable to experiments with a single subject. Frequently, however, a hypothesis cannot be adequately tested without obtaining data concerning control subjects. The collection of such data is extremely time-consuming but it is often possible to make use of published data such as norms for tests or scores reported in research papers. When this is impossible, it is sometimes useful to employ a single control subject. Thus it may be postulated that, for a certain individual, an abnormality of some complex function, *A*, results directly from impairment of some simpler, more basic function, *B*. If this individual and another, not displaying a dysfunction of *A*, are both tested in respect of *B* and the experimental subject scores no lower than the control subject, the hypothesis is then shown to be untenable. If, however, the control subject's score is superior extended control data will be required.

Our insistence on the independence of the psychologist's contribution to psychiatric practice is not meant to imply competition with the psychiatrist. On the contrary, it is suggested that the most appropriate role for a clinical psychologist, while not that of an assistant or technician, is that of an auxiliary scientist akin to a medical physicist or biochemist. The essential similarity with the latter professions tends to become obscured by the psychologist's much more extensive personal contacts with patients, which make his functions appear more truly clinical. Novel techniques in physical medicine, involving the use of radioactive materials, have recently had similar effects on the physicist's functions.

Psychiatric procedure may be conveniently considered in terms of the following stages—

1. The routine collection of data concerning the patient and his illness.
2. The evaluation of these data and the specification of further data required, hypotheses to be tested and problems to be investigated.
3. The carrying out of these additional investigations.
4. Diagnostic and prognostic evaluation, and making decisions concerning treatment or disposal.
5. Treatment.
6. Assessment of the effects of treatment.

These stages all refer to activity related to single patients, but it is important that, from experience with individual patients, generalizations of wider implication are formulated. Thus research must be included as a further category of psychiatric activity. It is claimed that the psychologist can be of assistance at each of these stages and the remainder of this chapter will be devoted to a description and exemplification of his role as here conceived.

THE PSYCHOLOGICAL DESCRIPTION OF PSYCHIATRIC PATIENTS

Routine Description

Relative status in terms of certain psychological functions is so frequently relevant to a patient's mode of adjustment that its routine measurement is advisable. Intellectual status is one such variable for most types of patient. For a child, the demands of his formal educational environment are so great, and play such an important role in his emotional adjustment, that knowledge of his levels of scholastic attainment is essential for a realistic appraisal of his difficulties. For this type of description, involving comparisons with people in general or with specific groups of people in terms of relatively well-defined dimensions, the use of standardized validated tests is both economical and efficient, provided that care is taken to ascertain that the standardization sample is representative of the relevant population. This is particularly important in Britain where many of the tests in common use were originally standardized in the U.S.A. The standardization data for several of these have been shown to apply fairly well to British populations but this cannot be assumed to be true of all. Ingham (1951), for example, found that a child patient achieved a very low score on Thurstone's Primary Mental Abilities test and a relatively high score on Raven's Matrices. Testing the hypothesis that this discrepancy resulted from slow speed of performance, Ingham administered both tests to the patient's classmates and found a large mean discrepancy in the same direction. When a test is administered deliberately out of its standardization context, common-sense judgements as to the implications of the score may be seriously in error. Thus Shapiro (1951) describes a young man who, though achieving a score well above the average on the Wechsler Intelligence Test, obtained almost zero scores on two oral reading comprehension tests standardized on young children. Further investigation showed, however, that large discrepancies in the same direction, though not to the same extent, were characteristic of a group of graduate psychologists.

With psychiatric patients, mental testing also presents difficulties related to the standardization of administration procedures. Such patients frequently co-operate badly or display emotional or other reactions which make it difficult to obtain responses in the usual manner. It is permissible, and an expression of his skill, for the psychologist to employ any appropriate devices, verbal or otherwise, in an attempt to allay the patient's anxieties and enlist his co-operation before the actual testing is commenced. If the standard procedure is modified during the actual test administration, the score obtained cannot be assessed in terms of the published norms. Minimal

changes sometimes have to be made in order to obtain a response at all. Thus a patient with speech difficulties may be required to point, instead of speak, in order to indicate his selections from among groups of multiple-choice responses. More gross and unsystematic modifications should be avoided until a normal administration of the test has given an indication of the patient's actual level of performance under standard conditions, though not necessarily of his potential. Readministration under altered conditions is essentially a test of an implicit hypothesis and, as such, belongs to the third procedural stage described earlier.

Error is inherent in all measurement and the errors of measurement resulting from imperfect reliability, validity and standardization, associated with even the most satisfactory tests, may be quite extensive. The resultant misclassification may be sufficiently small to be relatively unimportant for some group selection procedures but the clinician is, at any one time, concerned with only one individual for whom the results of misclassification may be serious. Of those individuals obtaining a median score on a test with a validity coefficient as high as 0.9, which is rare, some 10 per cent would be more correctly assigned at above the 70th or below the 30th percentile, without considering errors of sampling during the standardization of the test. Sometimes, errors in one direction may be more serious than those in the opposite direction as, for example, when incorrect inclusion within a "mental defective" category has more serious consequences for a patient's welfare than incorrect exclusion from the same category. Thus it is important that the psychologist considers not only the obtained score but the whole range of assessments consistent with this score and the probabilities associated with them. Payne and Jones (1957) discuss at length the statistical computations necessary for such consideration.

Many psychologists would include among their routine descriptive procedures some technique of personality assessment. If, however, objective procedures are used for this purpose they only provide measures of certain very restricted traits or, if of wider connotation, the errors of measurement are generally too large for individual assessment. Large claims are made by the proponents of the less objective "projection" techniques, such as the Rorschach, but the available evidence does little to substantiate these claims (cf. Payne, 1955). Whatever the merits of the techniques employed, there would be considerable overlap with the inquiries being carried out by the psychiatrist and the psychiatric social worker at this stage of investigation. It is more economical and

probably more efficient to confine the psychological investigations of personality factors to later attempts at solving specific problems.

For similar reasons it is considered inadvisable to employ a battery of tests covering a wide range of attributes at the routine descriptive stage of an investigation. Even if sufficient standardized validated tests were available, it would be virtually impossible to include measures of all the variables which might be relevant to the patient's disorder. In the field of learning alone, in which, as illustrated by later examples, psychiatric patients frequently display abnormalities of a rather specific nature, it would require at least sixty-four separate tests to vary at all adequately the sensory modality of presentation, the nature of the material in terms of verbal-non-verbal and sense-nonsense dichotomies, the difficulty level of the task and recognition and recall methods of testing. Increased time can only be granted to routine measurement at the expense of later specific investigations. One unfortunate consequence of this is the temptation to "over-interpret" one's test results, by deriving from them inferences additional to those justified by the validation data. Thus an individual's responses to items of the Terman-Merrill Binet test may suggest conclusions concerning his spatial ability, memory, or some other "partial" ability, but McNemar (1942) shows that the reliability of items is low and, even when both forms of the test are combined, no valid subscales, except for vocabulary, may be derived from the total scale. Similarly unjustified conclusions are frequently drawn from the degree of scatter or pattern of scores on many tests (cf. Jones, 1956b). Inferences concerning orectic factors may be suggested by the verbal content of a response, irrespective of its accuracy. All such inferences, however, are of the nature of hypotheses and require further validation.

Specific Investigations

After the collection of the limited quantity of data advocated in the last section, the psychologist meets with the psychiatrist, the social worker, and others concerned, for discussion and joint evaluation of all the available data concerning the patient and his problems. The broader theories of general and abnormal psychology will be the frame of reference for his contribution to this discussion. In all but cases of a most routine nature, and these are rare in psychiatry owing to the multiplicity of factors affecting symptomatology, discussion results in the specification of problem areas requiring further investigation before firm decisions can be made as to the treatment of the patient.

Descriptive measurement by means of standardized tests may again be necessary to assess the statistical abnormality of a patient's level in respect of some

function such as "manual dexterity," "extraversion," or "level of aspiration." This is easily determined if suitable tests are available with adequate norms for a population comparable with the patient in respect of such variables as age, sex and intelligence. Questions of validity, particularly the avoidance of "faculty error," are, however, especially important when using tests of relatively "narrow" functions of doubtful status in psychological theory. For example, if it is proposed to use a test of "perseveration," it is necessary to consider the evidence as to whether a general factor, several group factors, many relatively specific factors, or some combination of these, best accounts for the intercorrelations between tests of this function. When there is no evidence of a relevant general factor from intercorrelations within a normal population, it may still be reasonable to postulate that, for a particular patient, some pathological process has resulted in a tendency to respond in a particular way in a variety of test situations, but this hypothesis cannot be adequately tested by obtaining a score from any one standardized test. It is frequently necessary to compare the patient's performance, not with general norms, but with those for some specific population. For example, the patient may have suffered a neurotic breakdown during the early stages of a university course and questions are raised as to the adequacy of his intellectual or other equipment and his prospects of ultimate success. Earlier routine testing will have provided data relevant to these questions but much more precise information may be obtained from tests of attributes, interests, aptitudes and abilities shown to be relevant to the course in question, standardized on specific university populations and validated against criteria of success. Another patient might have developed a psychiatric illness shortly after the successful completion of such a course and the nature of his symptoms may be such as to suggest some deterioration of intellectual functions. The same tests might then be employed to assess whether the patient is now abnormal when compared with a population of which he was earlier a member.

Frequently, at this stage of an investigation, no standardized validated tests are available, which are capable of supplying the requisite information, or the hypotheses under consideration may refer, not to descriptive attributes, but to dynamic interrelationships between variables, which cannot be verified by simple measurement. Procedures of a more experimental nature must then be adopted and these are best described by exemplification. The descriptions of experimental investigations which follow include several concerned with abnormalities of learning in order to illustrate the wide range of specific disabilities which may occur within a single functional category

and to provide a link with the writer's earlier chapter concerned with this function.

Bartlet and Shapiro (1956) describe the investigation of a ten-year-old child with severe psychiatric symptoms including paranoid reactions, temper tantrums, lack of sociability, encopresis and enuresis. Despite adequate though below average scores on intelligence tests and special remedial treatment by competent teachers, he was very backward scholastically and, in particular, was unable to read the simplest of words. The reading disability assumed considerable clinical importance in that the patient continually expressed a strong desire to be able to read but displayed marked signs of anxiety in a teaching situation. The psychological investigations were focused on this abnormality.

The more usual diagnostic reading tests were of little value owing to the extreme nature of the disability but errors made in naming letters of the alphabet were suggestive of both auditory and visual discrimination difficulties. Specially designed tests of these functions, however, gave no indication of gross disability. It was then postulated that the dysfunction was basically one of learning or retention. This was tested in a situation, closely analogous to learning to read, by setting the patient and a single control subject (matched for age and intelligence but able to read) the task of associating spoken nonsense syllables with visually presented nonsense shapes, e.g. \int - *REZ*. Three series of three such pairs were learned to a criterion on successive days until no relearning was necessary. Retention was then tested after an interval of five days. There was a large and significant difference in favour of the control subject in terms of the number of trials required on the first day of testing, a similar but insignificant difference on the second day, but no differences on subsequent days. The control group was then extended by applying the first day's procedure for one of the series to a group of ten backward children. The scores obtained fell into two distinct groups, a low scoring group equivalent to the original control subject and a high scoring group equivalent to the patient. The latter group were all non-readers and all, like the patient, made errors in reading the alphabet. There was a clear difference between the two groups in the latter respect. Initial learning disabilities thus seem more widespread than would be judged from the literature.

The patient's disability was explored further in a second experiment, with the aim of providing indications as to the most suitable method for remedial teaching. Paired associates were again used but included visual, auditory and tactile-kinaesthetic material, associations being formed both within and between these modalities. The same control subject was employed and eight associations of each type were learned according to a complex experimental

design, which ensured that the daily task was small, and retention was tested over twenty-four hours. The results showed no difference between the patient and control subject in respect of learning visual-visual pairs, but there were highly significant differences, in favour of the control, within both other modalities. All cross-modality pairs produced significant differences, the probabilities ranking as would be predicted from the intra-modality results. During the retention phase, differences were insignificant for the intra-modality pairs but significant, though smaller than during the learning phase, for the cross-modality associations. Thus the results of the second experiment confirmed those of the first, in that initial learning difficulties were again evident, but these were shown not to apply to purely visual material. Unlike the first, the second experiment suggests difficulties of retention but, in this study, overlearning was prevented by use of interpolated material whereas, during the first experiment, the criterion applied to a series as a whole and allowed considerable overlearning of some pairs by the patient. The descriptive investigation was discontinued at this stage and the findings applied to the remedial treatment of the patient.

Inglis (1956) described the investigation of two cases along similar lines. One, a young woman referred for investigation as an "illiterate mental defective," achieved, in fact, a full scale Wechsler I.Q. of 82 but with a marked discrepancy between the Verbal (I.Q. 75) and performance (I.Q. 94) scales. Paired-associate learning tests gave evidence of a gross dysfunction but confined to the auditory modality. The second, an old lady of 72, was presented clinically as a case of "memory disorder." Although this term suggests a defect of retention, an experimental investigation demonstrated that the primary weakness lay in the process of acquisition and was common to the modalities tested and to both the recall and recognition methods of reproduction. Although tests of "immediate memory," such as digit span, are commonly used clinically with this type of patient, she achieved normal scores on tests of this function.

The investigation (Payne, 1957) of a young woman with a history of encephalitis and a severe "memory disorder" also indicated a disability of learning rather than one of retention, but this was confined to the learning of meaningful material such as words and pictures. Her ability to learn meaningless paired associates such as nonsense syllables or nonsense drawings was no worse than that of control subjects. It required a long series of experiments, controlling various other factors, before this generalization could be considered reliable and valid. The labour was reduced by the employment of tasks previously used in a research study and for which control data were available in published form.

In all these investigations the results indicated greater difficulties of acquisition than of retention. The reverse tended to be true of another case (Jones, 1957), a boy of eleven with a marked arithmetic disability. The discrepancy between his scores on verbal and performance tests of intelligence was abnormally large, with verbal ability little below average and performance ability little above the "defective" level. His scores on non-verbal tests appeared to be negatively correlated with the contributions of "spatial" and motor factors to the tests used. Investigations also gave evidence of a marked learning disability and this was maximal when the task was selected to include motor and spatial aspects (a stylus maze). Most striking, however, were his retention difficulties, which are best illustrated by data from the records of attempted remedial treatment over a period of four years. One of his major difficulties in making arithmetical computations was lack of knowledge of the multiplication tables. He could recite some of the tables in order, but only by making a series of mental additions. After two year's coaching for one hour a week, except for school holidays, he was still uncertain of forty-five of the hundred multiplication facts concerning numbers below ten. These were then arranged in random order to form nine series of five problems to be learned by the anticipation method. Two such series were learned to a criterion of three successive correct responses during each coaching session and no series was eliminated until the criterion was reached, without relearning, on three successive occasions. Results with the first series (4×5 , 6×3 , 5×6 , 8×4 , 9×5) are typical of his performance in general. He never required more than nine trials to achieve the criterion and, after five or six sessions, seldom more than four. It required a year's such practice, however, to achieve the criterion of retention, and deterioration in performance was noted immediately following a holiday period. When, at school leaving age, the patient stopped attending the clinic his knowledge of the multiplication tables was still far from complete.

Though the disabilities investigated during the studies outlined above have all been described as dysfunctions of learning, in only two instances was there a general impairment of learning for all the situations employed. The remainder might better be described in terms of the modality or other factor crucial to the demonstration of impairment, the learning nature of the task being considered merely as a convenient expression of the patient's ability in these conditions. This distinction is illustrated by an investigation of an adolescent girl who achieved a verbal I.Q. of 99 on the W.I.S.C. and a performance I.Q. of only 46. This is the largest discrepancy of this nature observed by the writer and, from the standard-

ization data, would only occur once in some 5,000 cases. A series of experimental results suggested that the patient's perceptual functioning was adequate for all modalities, and that mechanisms concerned with such functions as problem-solving and connexion forming were unimpaired but, whenever she was required to make an overt motor response relevant to these functions, its execution was inaccurate. Among the experiments performed was one involving the administration of "digit span" tasks to the patient and a control subject in the following ways: (1) digits presented orally for repetition by the subject; (2) printed digits presented visually for oral repetition by the subject; (3) visual presentation by patterns of dots, oral responses by the subject; (4) Knox cube presentation by tapping a sequence on four wooden blocks, motor repetition by the subject; (5) Knox cube presentation, as before, but with prior verbal allocation of numbers to the blocks, oral responses by the subject. Consistent with the other findings, the only appreciable difference in score resulted from the fourth condition but this cannot then be considered as evidence of some dysfunction of "memory span."

Beech (1957) made use of learning tasks for the experimental investigation of more dynamic hypotheses concerning a young man with apparently psychosomatic symptoms and a history of failure to complete a Science degree course at two universities. One of these institutions reported that he was lazy and pleasure-seeking, the other that he lacked ability. In fact, on tests of various relevant abilities, his scores were above average for a university population. Questionnaire measurement showed him to be highly introverted and his performance was entirely adequate on simple paired-associate learning tasks of the type described above. (After an interview with the patient it was postulated that one reason for his academic failure was a tendency to set unrealistically high goals and to overestimate his ability.) This was confirmed by use of "level of aspiration" techniques during performance of a laboratory "tracking" task. His overt emotional disturbance ("catastrophic reaction"), when he repeatedly failed to achieve his target, suggested the additional hypothesis that he was exceptionally susceptible to stress, particularly stress resulting from threat of failure. Given the mildly stressful task of learning, by serial anticipation, a list of nonsense syllables presented by means of a memory drum, the patient achieved a score 0.7 S.D. below the mean for a group of University students employed in a research project. When then told that his performance had been inferior but that the psychologist's evaluation would depend upon a second test, his score fell to -4.0 S.D. for an equivalent series. The hypothesis was further supported by the patient's differential performance on tasks which, though of

equal objective difficulty, were presented by the psychologist as of varying difficulty, and on tasks truly varying in objective difficulty.

Krikler and Shapiro (1957) found evidence of similar abnormal susceptibility to stress in a young male neurotic patient with study difficulties. Though achieving high scores relative to a university population on the Nufferno level and speed tests (cf. Chapters 5 by D. Furneaux and 6 by R. W. Payne), his relative speed of problem-solving declined appreciably, both when instructed to work fast and when presented with more difficult problems. Repetition of these and other intellectual tests resulted in improvements beyond those expected from practice. This suggested the hypothesis that, for this patient, novelty of the task was an additional stressor factor and this was confirmed in later experiments. The nature of some tests is such that the correctness of a subject's solution to a problem can be checked for accuracy before proceeding to the next problem. Other tests are essentially ambiguous in this respect, there being no external check on the correctness of a solution. It was noted and verified that the patient's performance was consistently superior on tests of the former type. Thus, while this patient and the previous one both reacted adversely to stress, the specific situations inductive of stress were different in the two cases.

In terms of the theories and empirical studies discussed at length in the chapter on learning, both these patients would be described as exhibiting high levels of drive. The reverse is true of an adolescent patient investigated by the writer (Jones, 1957). This boy was an inveterate truant and thief and his scholastic attainment, particularly in reading, was well below that predicted from his age and test intelligence, which was average. In view of his backwardness and generally extraverted pattern of behaviour, a learning disability was postulated but not confirmed by appropriate tests. Further experiments, however, gave evidence of other factors tending to reduce his cognitive efficiency. Compared with a group of adolescents tested during a research project, his speed of performance was slow but more striking was his relative lack of persistence when tested with Raven's progressive Matrices. His persistence fluctuated considerably: with relatively easy items he persisted a few seconds only and consequently made many errors. Thus, for the entire Matrices test his score was equivalent to an I.Q. of 87 but, when only the more difficult items were considered, his performance was at least average. This pattern of relatively worse performance with less difficult tasks was also evident from the learning tasks. He required five trials to learn a fairly simple stylus maze path and only six trials to learn a path of considerably greater complexity. The control group, on the average, required

more than twice as many trials with the second than with the first path.

Experimental methods may also be applied for the testing, by the psychologist, of hypotheses formulated by the psychiatrist and derived from psychiatric data. Walton (1957a) describes the application of "perceptual defence" techniques (cf. Chapter 7 by J. Inglis) in investigations of this nature. The psychiatric examination of one patient had produced evidence of three major sources of emotional disturbance; parent-child relationships, sexual adjustment and vocational adjustment. Before planning treatment it was important to decide which of these areas of difficulty was most relevant to the patient's illness and, to aid in reaching this decision, Walton carried out an experiment with the patient based on Rosenstock's (1951) technique. Eight sentences were constructed relating directly to the known emotional difficulties of the patient and two matched neutral sentences for use as controls. These were projected with three-second exposures at seven graded values of illumination. It was postulated that the control sentences would be perceived at lower levels of illumination and with fewer errors and distortions than the affectively loaded sentences. Among the latter, those related to the most disturbing area were expected to be differentiated by the same criteria operating in the reverse direction. There was no significant difference between scores for the neutral sentences and the total group of affective sentences but the difference in error scores between the neutral and parent-child sentences was highly significant. This suggested that the parent-child relationship might be the source of greatest disturbance, a conclusion supported by subsequent psychiatric and psychological investigations.

Beech (1957) has applied similar techniques to the testing of specific "psychodynamic" hypotheses concerning relationships between symptomatology and psychopathology. Thus *anorexia nervosa* is a condition considered by some to result from a rejection by the patient of her sexuality. Starving herself, such a patient denies her femininity by not allowing her figure to acquire feminine curves. This hypothesis implies the development of an association between stimuli concerned with food and those concerned with sexuality. Beech sought to verify such an association in his investigation of a young anorexic patient. After establishing the patient's auditory threshold, tones 5 db above that threshold were presented and immediately followed by the auditory presentation, 5 db below threshold, of words of either neutral or sexual connotation. The patient was instructed to respond to each tone by writing down the first word that came to mind, however foolish it seemed. It was predicted that words related to eating would occur more frequently during the presentation of subliminal

sexual stimulation than during the neutral subliminal stimulation. Such a trend was in fact observed to a degree just short of significance at the 5 per cent level.

Two investigations by Metcalfe illustrate a more direct experimental approach to problems of this nature. One (Metcalfe, 1956) was designed to test the hypothesis that a patient's asthmatic condition was related to emotional difficulties deriving from her relationship with her mother, and that individual attacks were precipitated by contacts with her mother. From a log including records of all the patient's attacks of asthma and her main day-to-day activities, it was possible to demonstrate a highly significant statistical relationship between the attacks and the patient's meetings with her mother, but the experimental presentation of stimuli associated with her mother had no similar effect. The second patient (*see* Shapiro, 1957) was a tiqueur and the hypothesis was tested that the frequency of the tics was increased in situations of specific stress defined by the psychiatrist. The actual frequency was recorded in such situations and in control situations of minimal stress. It was shown that the patient in fact produced the tic far more frequently in the latter situations.

Nosological Description

Psychiatrists, following the well-established procedures of general medicine, are much concerned to apply diagnostic labels to their patients and consequently, their descriptive investigations are largely directed to this end. Thus many of the specific problems presented to the psychologist for investigation refer to questions of diagnosis or, more frequently, questions of differential diagnosis between certain alternative nosological categories. In response to demands of this nature, many diagnostic tests have been developed and validated in terms of their power to differentiate between groups of patients selected, on psychiatric grounds, as typical of the categories to which they are assigned.

Payne (1958) has critically examined the rationale for diagnostic testing and points out that it is based on the assumption that, as in physical medicine, the diagnostic categories refer to qualitatively different and mutually incompatible disease entities. Much evidence, however, indicates that patients suffering from many of the so-called functional diseases are characterized by certain combinations of loci along unrelated psychological continua, equally applicable to the description of normal subjects (*cf.* Chapter 1 by H. J. Eysenck). Even if this basic assumption is considered valid, there remain various difficulties of a statistical nature in interpreting a particular diagnostic test score. Antecedent probabilities, deriving from differential "base rates" (*cf.* Meehl and Rosen, 1955), need to be taken into account before assigning a

patient to a particular category and these are usually impossible to assess for any particular clinic population. The magnitude of a particular test score may be used to determine the probability of correct assignment to a particular group but the nature of the validation procedure is seldom such that variations in score imply varying severities of disorder within that group: the scores of two patients may imply that one is more likely to be depressed than the other, but not that he is more depressed. A related difficulty arises from the fact that validation is based on typical patients, whereas psychologists are usually asked to test atypical patients with disorders difficult to diagnose by psychiatric criteria. The reliability of the criterion, psychiatric opinion, is itself low, and there is considerable variation among psychiatrists from different clinics as to the signs and symptoms indicative of a particular diagnostic category.

The value of a diagnostic label, Payne argues, lies in its practical implications. Unlike diagnoses in physical medicine, psychiatric diagnoses rarely imply a specific aetiology, because the aetiology of most psychiatric conditions is still a matter of speculation. They do, however, bear implications concerning prognosis and methods of treatment. They are also descriptive in that they imply the presence of at least some members of a specific cluster of symptoms. The reliabilities of and intercorrelations between tests and diagnoses, and the intercorrelations between diagnoses and their inferred consequences are, however, generally low. Thus the inference that a test score carries the same implications as the diagnosis against which it was validated is by no means certain. Payne therefore argues that tests should be validated directly against practical criteria related to such factors as specific symptomatology, prognosis, or the success of specific methods of treatment. Diagnostic tests, at their present stage of development, may be considered comparable with intelligence tests when validated against such criteria as teachers' ratings. Later developments in intelligence testing involved methods of internal validation and external validation against more objective criteria, such as success in examinations. Internal validation procedures applied to diagnostic tests have produced results incompatible with the use of the present external criterion and Payne advocates a change to external criteria of the second type.

Quite apart from such considerations, the employment by psychologists of diagnostic tests, derived from and interpreted within a framework of psychiatric concepts, is a violation of the principle of independent contribution described earlier, and unlikely to advance the development of psychological techniques and theory. A psychologist, examining the case-history of a neurotic patient, and adopting

as his frame of reference the type of aetiological theory described in the chapter on learning, will be less interested in the precise nosological category applicable to the patient than in such variables as his degree of neuroticism, his position on the introversion-extraversion dimension, the nature and amount of stress to which he has been subjected, the conditioned stimuli which evoke the abnormal reactions and the patient's characteristic emotional and instrumental responses to these stimuli and to situations of direct stress. This type of diagnostic evaluation by a formulation of the relevant characteristics of the patient, his past history and his environment is, in fact, advocated by many psychiatrists, and is common practice in child guidance clinics. Few objective techniques are available for the evaluation of these factors and practically none of sufficient reliability and validity for use with individual cases. Recourse must then be made to more experimental investigations, such as those described earlier. These may furnish leads for improved methods of routine measurement.

Frequently, description in terms of psychological variables may be more helpful than nosological information in terms of relevance to practical problems of prognosis, treatment or disposal. The first group of experimental investigations, described earlier, which gave evidence of specific disabilities confined to narrow zones of functioning were all suggestive of some form of cerebral damage or agenesis, and one of the patients concerned had a clear history of such a condition. It is doubtful, however, that a positive indication from a test of brain damage would have assisted the psychiatrist to any extent in his treatment of these cases. Frequently, too, problems posed by a psychiatrist in nosological terms cannot be solved by diagnostic tests, however efficient. This is illustrated by the investigation (Beech and Jones, 1957) of a middle-aged woman who complained of memory defect following a head injury received in a motor accident. She was suing for damages from the owner of the offending vehicle and there existed a strong possibility that the disability was simulated. She achieved very low scores on the Wechsler-Bellevue and Wechsler Memory Scales but her co-operation was suspect. Neither a test score indicative of brain damage nor, for example, a pattern of responses to the Rorschach cards, considered typical for malingerers, would have decided the issue.

If the patient was in fact falsifying her responses this should be evident in a situation where the information necessary for falsification was itself acquired within that situation. The learning of a serial T maze is a task of this nature. During the first trial the subject cannot know which of each pair of possible responses is correct but, during the course of successive trials, he gradually learns the correct and, equally, the

incorrect responses. A malingerer might then be expected to achieve scores significantly worse than those expected from chance selection of responses or, if extremely sophisticated, which this patient was not, to maintain an artificially equal frequency of correct and incorrect responses, or show gradual but slow improvement which does not follow the usual curve of learning, nor display the usual serial position effects. Thus the patient was told that her memory was to be tested and was presented with a series of ten cards, each with its central area painted either red or green in colour, the succession of colours to be learned by serial anticipation. Though relatively slow in learning this simple series, she achieved the criterion of one correct reproduction and her pattern of improvement was in no way abnormal. It was therefore considered unlikely that the disability was simulated.

Assessment of the Effects of Treatment

The discussion so far has been concerned with the psychological description of patients as they present themselves at a clinic but the main function of a clinic is treatment. It is, therefore, important to develop objective methods of describing relevant changes in a patient's modes of functioning in order to assess the efficacy of the treatment applied. An earlier chapter was devoted to a consideration of the evidence concerning the effects of psychotherapy and the discussion there illustrated the difficulties of establishing satisfactory criteria of improvement and cure. These difficulties are even greater when a single patient is considered in isolation, and a thorough evaluation of all the effects of a particular treatment is scarcely possible. It is frequently possible, however, to trace changes in status in terms of specific measures shown to reflect changes in a patient's general clinical condition or related to specified aims of the therapist. Earlier investigations will often suggest such measures as in the cases, described previously, of patients shown to react abnormally to various stresses of a specific nature. Effective therapy with these patients should modify these reactions and such a modification could be demonstrated by measuring performance during fresh presentations of the original stress situations.

Souef, Shapiro and Martin (1957) attempted to measure the effects of leucotomy on a depressed, anxious and obsessional patient, who also complained of excessive and persistent muscular tension. Before the operation, scores on the Hildreth Scale for Feelings and Attitudes, the Taylor Manifest Anxiety Scale and a specially designed questionnaire, based on the patient's case-notes, were all consistent with extreme anxiety and depression. An experimental measure of the frequency and duration of "obsessional" thoughts was taken during rest and when carrying out a mental

arithmetic task. Measures of muscular tension were obtained during rest and when the patient was responding orally to very simple arithmetical questions and to questions concerned with her symptomatology. Her initial resting level of tension was not significantly higher than that of control subjects but showed an abnormally large increase in both activity conditions, and remained high when the questioning ended. When retested after the operation, the scores related to anxiety, depression and obsessional thinking were well within normal ranges, but the muscle tension measures showed no significant change for the activity conditions and a significant rise under the initial rest conditions. An intended retest some months after the operation could not be carried out owing to the patient's refusal to co-operate.

Payne (1956) studied an interesting side-effect of treatment with Antabuse on a man with a history of delirium tremens and polyneuritis. A psychiatric colleague had noted that an earlier patient, with possible organic impairment, had shown signs of intellectual deterioration when treated in this way and

postulated that in a patient already brain-damaged, Antabuse produced further deterioration. Before treatment, the second patient achieved scores within the average range on several tests of intelligence and tests of paired-associate learning in various modalities: he was below average in numerical and motor abilities. He was retested after receiving Antabuse treatment for three weeks and showed a marked decline in learning ability, especially for learning new verbal material in the auditory modality. There was no deterioration evident in the other abilities tested, his scores increasing to a degree consistent with normal practice effects. The patient was discharged and readmitted a few weeks later with peripheral neuritis. His learning ability was retested six weeks following the first retest and three days after his last dose of Antabuse. His scores were equivalent to those on the second occasion but, when tested seven weeks later, his learning ability was again normal. Similar investigations of other patients has confirmed this temporary effect of Antabuse treatment on learning ability.

PSYCHOLOGICAL TREATMENT

The methods, generalizations and theories of psychology are as applicable to the treatment of psychiatric disorders as to their description. Each of the descriptive investigations reported in the previous section resulted in generalizations concerning aspects of the patient's functioning, with implications for his treatment or appropriate disposal: if the original hypotheses had not carried such implications they would not have been tested. Frequently the methods of treatment suggested by such descriptions of patients' abnormalities in psychological terms involve essentially psychological techniques, and the psychologist may then be the most appropriate therapist.

This is well illustrated by the treatment, by Bartlett, of the boy with severe psychiatric symptoms and a gross reading disability, the investigation of which was described earlier. Owing to his strong motivation, treatment was directed towards teaching him to read and was carried out by the psychologist. The results of the experimental investigation implied that the remedial method should maximize the use of visual material and foster the development of visual associations. It also seemed important that the initial units learned should be small, few of these should be presented during any one session, and overlearning should be encouraged by plentiful revision. For the latter reasons an analytic method was employed, the sounds of letters being learned first and then larger phonograms. Irregular words were introduced relatively late and these were also analysed into smaller

units. Such a method is not usually predominantly visual in nature but the Moxon method (cf. Bartlett and Shapiro, 1956) is essentially analytic-synthetic and yet depends largely on the association of letter sounds with pictorial material. An adaptation of this method was used in the remedial treatment, which took place during daily half-hour sessions over a period of six months. His score on a graded word reading test was then equivalent to a reading age of 7 years 1 month and equivalent to 9 years for a simple prose comprehension test. His psychiatric condition had improved remarkably and, towards the end of this period, though living in the hospital, he attended a normal day school. He then returned home and attended the local school, where he continued to make good scholastic progress and his behaviour created no difficulties.

Specific remedial techniques of this nature, based on careful behavioural analyses of dysfunctions, should find ready application in the re-education of patients displaying psychological deficits caused by brain lesions resulting from injury, disease, or surgical intervention. Many such deficits involve symbolic functions such as language and recovery is then generally considered to imply the transfer of functions to the equivalent anatomical areas in the nondominant cerebral hemisphere. If so, it should be possible to facilitate this transfer by appropriate techniques. Thus a patient with an acquired alexia, but no hemianopsia, might well recover more rapidly if reading

material was at first presented only in one half of the visual field, or even in the form of mirror writing.

Stammering is a dysfunction generally considered to be symptomatic of a primary emotional disorder and, therefore, best treated psychotherapeutically. An alternative approach derives from the work of Cherry and Sayers (1956) who assume that speech production involves a closed-cycle feed-back system, enabling the speaker to monitor his own speech. They postulate that stammering is a form of relaxation oscillation resulting from instability of the feed-back loop. Consistent with this hypothesis, they find that prevention of the self-monitoring process by a masking continuous tone inhibits stammering but agree with earlier workers that inhibition in this way is temporary only and unlikely to be of therapeutic value. They obtained similar effects by forcing the stammerer to listen to the voice of another speaker while speaking himself. This is most easily achieved by a "shadowing" technique, the experimenter reading from a book while the stammerer shadows him without seeing the text. Practice at shadowing has the effect of training stammerers into new perceptual habits and may be of great therapeutic value. Marland, in an appendix to the paper cited, reports promising results with a wide range of patients during preliminary clinical trials and Meyer (1956) found the technique similarly effective for the treatment of two psychiatric patients with severe chronic stammers.

(Patients with perceptual dysfunctions of an "hysterical" nature fail to become consciously aware of certain classes of stimuli but these stimuli do in fact initiate various involuntary responses, frequently physiological in nature, of which the patient is unaware. Implicit in many reports, and of considerable importance from a therapeutic viewpoint, is the generalization that, if these patients are made aware of such responses, and thereby presented with a demonstration of the fact that the stimulation does in some way affect them, they may recover the lost perceptual function. A technique of this nature was utilized by members of the Psychology Department of the University of Minnesota for the treatment of a patient with hysterical deafness and was described in a broadcast, of which the writer was privileged to hear a recording. The critical stage of this treatment involved the demonstration to the patient of her own galvanic skin responses in response to speech sounds. Unfortunately, however, the situation was so manipulated as to induce in the patient a simultaneous emotional abreaction and the independent effects of these two factors cannot be evaluated. ✓

Complicating factors of this nature are less evident in the ingenious treatment of a patient with an hysterical glove paralysis and anaesthesia of one arm described by Hilgard and Marquis (1940). They

attached electrodes to both hands of the patient and, during the first phase of treatment, repeatedly applied shock to the normal hand as the unconditioned stimulus for finger withdrawal. These shocks were preceded by similar shocks applied to the anaesthetic hand and which acted as conditioned stimuli. The patient could observe the conditioned responses and sensitivity returned gradually to the affected hand. The conditioning procedure was then reversed, a conditioned stimulus of very weak shock being applied to the normal hand and followed by an unconditioned stimulus of strong shock to the paralysed hand. During the course of successive stimulations the affected arm gradually recovered powers of movement and conditioned withdrawal responses occurred. Theoretical explanations of this type of phenomenon are lacking but there is no reason why they should not be utilized for empirical treatments.

The examples of treatments so far described have been based on generalizations concerning the malfunctions of single patients or restricted groups of patients. Similar use may be made of broad psychological theories applicable to a wide range of patients. In the chapter on learning the writer discussed at length a theory concerning the aetiology of neurosis based on theories of learning. In terms of this type of theory, neuroses are behavioural abnormalities which include ideational response components but do not derive from some psychic entity lying behind the symptomatic manifestations. If this analysis is valid all treatment must be symptomatic: if all symptoms are removed so is the neurosis. It is true that, if only instrumental acts mediated by a conditioned avoidance drive (C.A.D.) are removed, the aversive drive tendencies will remain and, from the theory, one would predict that new instrumental acts would be reinforced and become habitual. This may be the foundation of the clinical belief in symptom substitution. In these instances the elimination of the C.A.D. responses themselves is also necessary. Some instrumental acts are themselves, however, the stimuli from which these responses derive. In writer's cramp, for example, the origin of the tremor may have been the result of a transient emotional disturbance. The disturbed writing behaviour could, however, lead to embarrassment and stress and, therefore, generate increased anxiety which would become conditioned to the various stimuli associated with preparation for writing. Liversedge (1957) has described a method by which this condition was symptomatically treated in a group of patients with no evidence of symptom substitution (*see also* Liversedge and Sylvester, 1955). The same is true of certain other well defined symptom entities such as nocturnal enuresis when treated symptomatically.

As to techniques of treatment, as modification of

behaviour is the aim, the generalizations of learning theory should provide the necessary guidance. Indeed, from one point of view, treatment may be considered as a problem in eliminating specific behaviour as presented and without reference to the causes and circumstances of their development and, where there is a circumscribed symptomatic entity with clear-cut stimuli defined by the situation, as in the example quoted of writer's cramp, this approach may be adequate. In other instances, however, various remote stimuli are of such importance that a knowledge of the history of the condition is important. In either case the emphasis is placed on observable behaviour rather than on underlying forces of a psychic nature and the treatments suggested may be better described as "behaviour therapy" than "psychotherapy" (cf. Chapter 1 by H. J. Eysenck and Eysenck, 1959).

Various experimental circumstances result in the decrement or elimination of responses. Each may provide an analogous therapeutic situation.

Punishment. Thorndike postulated a negative law of effect as well as a positive, and punishment is frequently used in everyday life to control disapproved behaviour. The work of Estes (1944) and others suggests, however, that punishment merely produces a temporary interference with ongoing behaviour and does not reduce the probability of its evocation on future occasions. In this connexion we need to distinguish between punishment and escape from punishment, a rewarding situation often confused with punishment. Even if effective, punishment would be an undesirable technique for dealing with responses mediated by a C.A.D. as the punishment itself would produce further stress and anxiety, which would summate with that already present.

Removal of unconditioned and conditioned stimuli. In the absence of the relevant stimuli, potential responses are not evoked and, in the long term, a process of forgetting or decay of habit strength may occur. This is precisely the rationale of Meyerian treatment by environmental manipulation, illustrated by the extensive social and educational modification carried out in child guidance clinics.

Satiation. Massed evocation of a response without reinforcement results in extinction of that response. After an interval, the response reappears owing to the phenomenon of reminiscence. Repeated massed extinction trials ultimately eliminate the response. This technique was adapted to the treatment of tics by Dunlap (1932), but his work has been largely ignored. Recently the writer has collaborated with Yates (1957) in attempting to eliminate a set of multiple tics in a young woman by this method. These tics are allied to respiratory movements and appear to have started following traumatic experiences while

undergoing anaesthesia. During treatment sessions the patient voluntarily reproduces the tics as accurately as possible, and over prolonged periods of massed practice. Predictions on the basis of learning theory have been verified in this situation, but it has required considerable experimentation to establish the optimal conditions for the development of conditioned inhibition. At the present time her voluntary responses have been much affected by inhibition, and there is a concomitant decline in her involuntary tics and a general improvement in her clinical condition. The questions still remain as to whether her tics will entirely disappear before or when conditioned inhibition of the voluntary responses is complete, and whether their disappearance, if it occurs, will still leave her with anxiety symptoms. This patient's pattern of tics is extremely complex and was arbitrarily divided into components for separate massed practice. Since the completion of the initial experiments, Pickersgill (1957), adopting the same method, has successfully treated two patients with severe and chronic tics but less complex in form and more easily reproducible.

The modification of expectations. Contemporary learning theories take into account the mediation of responses by goal expectancies built up from experience of the reinforcing situations. When expectations are not fulfilled, as when the reinforcement situation is altered, new expectancies are developed and new instrumental behaviour mediated. Thus it might be thought that, if the neurotic individual was forced or persuaded to remain in feared situations or to carry out feared acts, he would discover that the feared consequences no longer occurred. He would, however, meet the painful consequences of the unchecked arousal of the C.A.D., a response which it is extremely difficult to extinguish. When traumatically trained animals are forced to reality test in this way, little modification of avoidance responses occurs. This is consistent with the fact that a patient with a severe phobia or obsession is quite well aware that his anxieties are unrealistic.

The strengthening of incompatible reactions. If one response, incompatible with another, is conditioned to the same stimulus as the latter, and the new connexion progressively strengthened, the probability of evocation of the old response is progressively decreased, and will ultimately reach zero. This is the most promising method of response decrement for clinical application because emotional responses incompatible with anxiety and similar states are available in addition to incompatible instrumental responses.

One form of incompatible response is the opposite of the one to be eliminated. Actual inhibition of a muscular response is an example of this and is the

principle underlying the well-known conditioning treatment of enuresis (Mowrer and Mowrer, 1938; Davidson and Douglass, 1950). The enuretic responds by urinating to the stimulus of a full bladder. During treatment the same stimulus, the full bladder, is linked with a waking stimulus, a bell operated electrically at the commencement of urination. Urination responses are spontaneously inhibited on waking, and this inhibition, by a conditioning process, ultimately occurs spontaneously without waking and without sounding the bell.

Of a similar nature is Liversedge's method for the treatment of writer's cramp mentioned previously. He considers this symptom to be a form of conditioned response and the treatment is essentially a process of counter-conditioning. The cramp includes both tremor and spasm components and these are treated separately. During the "tremor" stage the patient repeatedly inserts a stylus into the progressively smaller holes of a steadiness tester. If contact is made with the edge of a hole, a circuit is completed which applies shock to the patient's *free* hand. After training with the steadiness tester the patient traces straight, curved and zigzag shapes with the stylus, deviations from the pattern resulting in shock as before. To counteract the spasm component the patient writes with a specially constructed pen. Excessive pressure with the thumb of the writing hand completes a circuit and the usual shock to the free hand is experienced. In the paper cited, Liversedge reports excellent results with a large series of patients.

Therapeutic techniques based on relaxation (cf. Jacobson, 1938) have an essentially similar rationale, as has Meige and Feindel's (1907) technique for the treatment of tics, employing graduated exercises involving the immobilization of the muscles contracted during the tic. These exercises are combined, however, with others involving active muscular responses incompatible with the execution of the tic. Such use of responses essentially different from the one treated, but chosen so that the same response systems are involved and the two responses cannot occur simultaneously, considerably extend the possibilities of this approach, especially for the modification of emotional responses.

Extensive use of treatment of this nature has been made by Wolpe (1954, 1958) who claims a high degree of therapeutic success for a wide range of neurotic conditions. It is doubtful whether all the methods he describes, which include such diverse techniques as carbon dioxide inhalation and emotional abreaction, may legitimately be included within his general category of "reciprocal inhibition" but many certainly do and clearly illustrate the rationale described above. Thus one of his subsidiary techniques is based on the expectation that, if an unpleasant emotional state

comes to an end immediately following the presentation of some stimulus, that stimulus will become conditioned to the "relief" responses following and incompatible with the unpleasant emotions. In this way the stimulus should acquire the capacity to inhibit unpleasant emotions arising in new situations. In practice Wolpe applies a continuous shock to the patient's left forearm, instructing him to tolerate it for as long as possible and then to say "calm." Immediately following this utterance, the current is disconnected and the process repeated some ten to twenty times in a session. Wolpe claims that most subjects report a strong feeling of relief with the cessation of shock, out of proportion to the disturbance produced by the shock. After several sessions, the patient's use of the word "calm" when emotionally disturbed in everyday life decreases the anxiety experienced and this effect becomes progressively stronger.

When, however, a response mediated by a strong C.A.D. is involved it is extremely difficult to initiate and sustain alternative behaviour. Even if this were possible, intense conflicts would ensue which might themselves be the source of additional anxiety. It is in these instances that use needs to be made of the generalization continuum in order to reduce the response potential of the undesirable response. At the same time, stimulation and motivation associated with the alternative response is enhanced. In these circumstances the alternative reaction becomes prepotent and, owing to its own generalization gradient, the process can be repeated nearer the centre of activity of the response to be treated. By moving along the generalization gradient in this way, the alternative response ultimately becomes prepotent in all circumstances. This technique has an experimental foundation in Wolpe's (1952) animal experiments and is essentially the method advocated by Jersild and Holmes (1935) for treating children's fears. Thus a child, afraid of dogs, is given a puppy. The puppy is sufficiently unlike a grown dog to elicit the fear to a small degree only. The puppy's antics create pleasurable responses and, as the puppy grows into a dog, this attitude spreads to all dogs. Desensitization procedures fit this pattern. Thus a certain concentration of allergen may inevitably result in an asthmatic attack. With practice at tolerating a concentration just below the threshold, however, the concentration can be gradually increased without precipitating an attack.

An interesting modification of desensitization procedures was involved in the treatment of a case described fully elsewhere (Jones, 1956). A young professional dancer had been forced to give up her stage career by reason of a disabling frequency of micturition with associated secondary fears and lack of confidence. Bykov (1953) reports a study in which

warm water was introduced into the bladder of human subjects, the pressure changes being displayed on a manometer placed before the subject. This manometer could be disconnected without the subject's knowledge. Subjects rapidly developed a conditioned "connexion" between the manometer reading equivalent to their original threshold pressure and the actual urge to urinate. An intense urinary urge and a galvanic skin response could be elicited merely by calling out the critical manometer reading. Conversely, if the manometer was disconnected, far greater quantities of fluid than normally produced urination could be introduced without evoking the urgency response. In the light of this report a similar apparatus was constructed and, by a combination of desensitization procedures and conditioned inhibition of the urgency response achieved by falsification of the manometer readings, the patient's bladder responses were greatly modified and her urinary symptoms disappeared. No other symptoms were then evident in the hospital, which she attended on a day-to-day basis, but the prospect of venturing into the street still induced a strong anxiety reaction, which was treated on the lines described above by instituting a daily programme in several stages. In a secluded roof-garden, the patient first embarked alone on a training course of limbering-up exercises to make her fit for dancing. She then devised and rehearsed a dance routine, first concentrating on the movements and then on acting as if before an audience. She was encouraged to imagine such an audience and to live the part as actively as possible. She then acted before the writer and finally performed successfully in a public non-professional stage show. Parallel with this training she made unrehearsed and progressively more extensive outdoor expeditions. A successful outcome has now survived a follow-up period of several years.

Another example (Carpenter and Jones, 1956), illustrating the separate treatment of somatic and emotional symptoms, concerns a male patient who exhibited a marked tremor, associated with anxiety, and particularly evident when the patient had to write in front of others, especially his superiors at work, where he was a pay clerk. The tremor also occurred when holding a cup or glass in public, and in other similar situations. At the time the patient was first seen, the tremor was almost chronic. As the main symptom was somewhat akin to writer's cramp, the conditioning treatment described by Liversedge was applied. At the beginning of treatment the tremor was very marked, and the patient was unable to place the stylus in the largest hole of the tester. A regular learning curve was produced, and at the end of this phase the patient's skill with this apparatus was well above that of an untrained normal person. There was also a general improvement in his condition.

Even so, on those occasions when he had to sign documents in the office of his superior, his anxiety was intense and the tremor reappeared. The generalization technique was employed with considerable success. Each day the patient carried out a task involving writing behaviour in public, but where the social consequences of failure were not serious and withdrawal to privacy was possible. Thus, for example, he might take a cheque to pay into his bank account and deliberately fail to endorse it. When the cashier pointed this out and requested his signature, the patient would be prepared and could, if overwhelmed with anxiety, retire to a writing booth. This case has been followed up for well over a year without relapse.

Walton (1958) combined the generalization technique with that of Cherry and Sayers in treating a stammerer who became very anxious and increased his stammer when forced to use a telephone, especially at work. The patient was taught to "shadow" and, when competent, repeated, by shadowing, to one psychologist in the room with him, the message received by telephone from a second psychologist. At a later stage this procedure was reversed, the psychologist in the room dictating the message and the patient shadowing, via the telephone, to the other psychologist. The final stage involved a graded series of unshadowed telephone conversations. Throughout this training objective records showed a steady improvement in the patient's speech with temporary partial relapses after the introduction of each new stage.

The treatment of two phobic cases by Meyer (1957) demonstrates the importance of individual differences in personality structure and the manner in which such differences dictate modifications of this type of therapeutic technique. One patient, suffering from blackouts and under investigation for suspected temporal lobe epilepsy, also complained of fear of going out on her own and occasionally with others. The latter symptom responded well to a graded re-education programme over a period of five weeks, similar to that during the later phases of the treatment of the dancer, described earlier. The second patient, a man, also suffered from blackouts and complained of excessive tension and various fears mainly related to entering enclosed and crowded places such as cinemas. As his fears seemed less specific than those of the other patient, he was treated by Wolpe's method for conditioning anxiety-relief responses to the word "calm," and concurrently embarked on a graded programme involving short daily visits to the local cinema at progressively later hours so that the cinema became progressively more crowded. After seven days he showed no improvement and continued to feel anxious in the cinema. Despite the similarity

of symptomatology this response was very different from that of the first patient. In terms of Eysenck's theory concerning the relationships between personality and learning (cf. Chapters 12 by C. Franks and 13 by H. Gwynne Jones) it was postulated that, though both patients would score high on tests of neuroticism, the second, compared with the first, would be considerably more extraverted and condition less readily in a laboratory situation. This was confirmed by scores on appropriate personality inventories and a measure of eye-blink conditionability. On the basis of the theory that excitant drugs increase condition-ability, the second patient was then given 10 mg of Dexedrine each day and, after four days, the earlier procedure was repeated and achieved rapid success. The dosage of Dexedrine was reduced progressively, being replaced with *placebo*. *Placebo* tablets were taken until his discharge after some five weeks of treatment.

Herzberg (1941, 1945) reports good results with a large group of patients treated by a technique involving graduated everyday tasks of a similar nature but real life situations may not be necessary in all cases, at least during the early stages of treatment. Psychodrama may well be adapted to this theoretical formulation. Unlike psychotherapeutically orientated psychodrama, this will not involve the "acting out" of existing attitudes and responses but their suppression by alternative incompatible responses from the earliest stages.

In chronic and widely generalized conditions it may be extremely difficult to find a situation in which an adverse emotional response is sufficiently weak to be superseded. This is true of a female patient at present being treated by the writer and with a long history of intractable fears, obsessions and compulsions. Despite hospitalization, pharmacological treatment and protracted attempts to treat this condition along lines similar to those described, progress was extremely slow and no situation could be discovered in which the patient was truly "at ease." Much better progress is now being made after the adoption of a procedure combining two of Wolpe's techniques. During each treatment session the patient is hypnotized and, being a good subject, does achieve a truly relaxed state. When in a deep trance it is suggested that she is in various situations known to be traumatic for her. If possible, situations are chosen which she is likely to experience in actuality within a short time. When she shows signs of disturbance she is instructed to say "calm" and suggestions of appropriate sensations of tranquillity and ease are made. The only post-hypnotic suggestion made is that, when she wakes up, she will not remember the traumatic situations but only the calmness and how, when she says "calm," she does in fact become calm. Her use of this word

in life situations is now becoming progressively more effective but she is still vulnerable to many such situations.

Removal of "manipulanda." Another possible method of response decrement, essentially similar to the last, is to eliminate from the stimulus situation those aspects necessary for the performance of the undesired response, while the remainder of the stimulation remains intact. Thus, if a rat spends much time in a Skinner box, from which the bar is removed, earlier learned bar-pressing responses will be eliminated (Hurwitz, 1955). Similarly, if the tremulous patient, previously described, had been able to spend a considerable period each day with his employer, but without being required to write, a later demand for his signature might have produced no marked effect.

Throughout this discussion fairly obvious and rather mechanical applications of therapeutic principles have been stressed but verbal interactions between therapist and patient may equally well be manipulated along these lines. The concept of "transference" might well fit into this conceptual framework: the therapist will presumably lie somewhere along the stimulus generalization continuum derived from, for example, the patient's father, and will therefore elicit responses learned in relation with the father. In so far as these responses become modified, the new responses generalize back to the father. Shoben (1949) claims that all psychotherapeutic procedures make use of three interrelated psychological processes: (1) the lifting of repression and the development of insight through the symbolic reinstatement of stimuli producing anxiety; (2) the diminution of anxiety by counter-conditioning from the attachment of these stimuli to "comfort" reactions induced by the therapeutic relationship; (3) re-education by helping the patient to form rational goals and develop appropriate behavioural methods for their achievement. The last two of these processes are clearly involved in the procedures described here and the main difference between "behaviour therapy" and "psychotherapy" lies in the emphasis placed on the first. The principles outlined here tend to indicate more active treatment than is usual in psychotherapy and would focus attention on the development of new responses rather than on the "understanding" of old responses.

It needs to be stated that, though the apparently successful treatment of a few cases has been described, other cases, treated on similar lines, have not been successful. It is not claimed that the remainder necessarily improved as a result of the treatment received, nor that behavioural retraining techniques are superior to psychotherapeutic procedures. What is claimed is the possibility of devising treatments derived from the findings of experimental psychology,

in line with the view here expressed concerning the role of the psychologist. Large-scale controlled studies involving such treatments would be necessary to establish their efficacy and the limits of their application. The reported results of workers such as Wolpe and Herzberg encourage some optimism as to the results of such an investigation.

No specific mention has been made of the treatment of psychotic patients because neither the writer nor any of his colleagues has direct experience of such treatment. Though the aetiology of these conditions may not involve learning processes, many forms of treatment will involve such principles of learning as the graduation and spacing of practice. These principles are clearly operative in the work described in recent reports on the rehabilitation of chronic psychotic patients by vocational and other training programmes within hospitals. There is also evidence that practice with tasks of graduated difficulty has a generalized therapeutic effect on psychotic patients, as shown by the work of Peters and Jenkins (1954).

Two recent reports illustrate the specific treatment of non-neurotic symptoms by techniques closely akin to those described here. Cowden and Brown (1956) were interested in the relationship between hypochondriasis and schizophrenia and the various psychological advantages gained by schizophrenics from the possession of a physical symptom. To test their hypotheses concerning this relationship, they

attempted to relieve a schizophrenic patient of his psychotic symptoms by replacing them with a physical symptom. The symptom chosen was a backache, consistent with an earlier injury to the patient's back. For a period of three months all members of the staff who had contact with the patient focused his attention on his injured back, which was "investigated" and "treated" with great care. At the end of this period, though showing little change in personality, the patient was convinced that his difficulties derived from his back injury and was free of psychotic symptoms.

Efron (1957) describes a patient whose uncinate seizures could be arrested by a strong olfactory stimulus applied at a certain stage during the development of the aura. Conditioned inhibition to a non-specific stimulus was then established by presenting an appropriate odour simultaneously with a visual stimulus in the form of a silvered bracelet. After eight days' training, the bracelet, when presented alone, produced a vivid experience of the odour. Thereafter, the bracelet was as effective in inhibiting the seizures as the olfactory stimulus had been previously and, at a later stage, the mere act of "thinking about the bracelet" was equally effective. Still later, there was evidence that fits were spontaneously inhibited and, for some time, this inhibition coincided with a spontaneous hallucination of the specific odour used for the treatment.

RESEARCH

The type of experimental clinical investigation advocated earlier is, in essence, a form of research carried out on a single patient and producing results which are then applied in further procedures with that patient. Patients seldom display unique abnormalities, however, and generalizations found to be applicable to a single patient may apply equally to a large group of patients. The testing of hypotheses with general implications may well be carried out as and when appropriate patients present themselves in the course of clinical work, the assessment of results being postponed until a group sufficiently large has been collected. The slow pace of research of this nature may even be advantageous in that it allows time for the careful matching of control subjects. Generalizations established in this way, not only furnish data relevant to theories of abnormal psychology, but enable clinical investigations to be made with greater economy of effort in that standard techniques of testing hypotheses are provided and control data is made available.

An example of such clinical research developing from one of the single case investigations described in

this chapter is provided by Inglis (1957). His (1956) findings concerning the elderly woman with "memory disorder" were later shown to have a considerable degree of generality. Other similar patients were tested, together with control patients, carefully matched in age and verbal intelligence but *not* showing any memory disorder. Three major findings emerge from this study: (1) scores on tasks akin to digit span are not affected by memory disorder; (2) failure in the acquisition of material is at least as important in memory disorder as poor retention; (3) disorders of learning in elderly people appear to be associated with disturbances of some intellectual functions. A further investigation is now in progress with the aim of confirming these findings and relating memory failure to disturbances of conceptual usage in elderly psychiatric patients (Inglis, 1959).

Apart from research of this nature, closely related to his practical clinical work, a clinical psychologist may be usefully employed in more formal research projects. One type of project, entirely appropriate to his function, may well fit the term "operational research." Projects in this category would be

concerned with such matters as the validation of some diagnostic procedure or the assessment of the effects of some form of therapy.

Other projects would be more of the nature of "pure" research in the field of abnormal psychology. Advances in the practice of clinical psychology are largely dependent upon advances in fundamental research and many would claim that, in the present state of knowledge, the most useful function of a psychologist in a psychiatric institution is the prosecu-

tion of basic research. Practical clinical work, if allied with appropriate reading of the research literature, can be one of the most fruitful sources of hypotheses concerning the nature of psychological abnormalities and clinical psychologists can and have contributed much to research in this area.

From the nature of his training, a psychologist may also contribute to the research carried out by psychiatrists, by advising on such matters as the design of experiments and the statistical evaluation of results.

CONCLUDING DISCUSSION

One characteristic of the approach to clinical psychology advocated in this chapter is the stress placed on objective methods of observation and the testing of hypotheses. This is not meant to imply that the psychologist should refrain from making a judgement on the basis of inadequate data. Time and other economic factors are of considerable importance in clinical work, and decisions of importance may have to be made when hypotheses are untested or partially tested. The hypothesis which seems most likely to prove useful then becomes a working hypothesis, on the basis of which action is planned or an opinion given. This does not imply a violation of scientific procedure as research can only demonstrate the falsity of a generalization and never its truth.

Many of the investigations and treatment procedures described here were extremely time-consuming. Apart from that spent with the patients, much time was frequently required for the preparation of apparatus and material, the collection of control data, the reading of relevant reports and the assessment of results. It is not suggested that the bulk of a psychologist's clinical work should be of this nature, nor that he should make a major contribution to the investigation or treatment of every patient: many will present few problems relevant to his functions. Even so, it is unfortunate that, with normal staff complements and the usual pressure of routine commitments, a psychologist can rarely undertake more than one or two long-term investigations at any one time. In ideal circumstances, a clinical unit dealing with some twenty neurotic patients would fully occupy the working time of one psychologist.

Another characteristic of this approach is its apparent disregard of the holistic nature of a patient's personality. The investigations and treatments described were all concerned with partial aspects of the patient's functioning and, in several instances, the aspect studied was apparently unrelated to the complaint which brought the patient to hospital. This is not to deny that an individual is unique nor that, in certain respects, one deals with and "knows" another

individual in holistic terms. Description and certainly measurement are, however, impossible without attempting to analyse the personality into its partial aspects, as is evident from the personality reports of clinical psychologists of holistic persuasion. Equally, to treat a patient's difficulties, one must consider partial aspects of his functioning, related though they be to other aspects, and attempt to bring them under control. Indeed, by very reason of these interrelationships, modification of partial aspects results in modification of the whole individual. The art of a psychologist may lie in his ability to deal with individuals but his science consists in analysing the complexities which go to make up individuality.

Index of Subjects

- ABANDONMENT (of problems), 174-92
 Ability —
 to abstract, 542
 to introspect, 583
 Abnormal behaviour in animals, definition of, 727
 Abnormal behaviour in wild animals, 748
 Abnormal child, 394
 Abnormal fixations, 726
 Abnormal sexuality, 739
 Abnormality, xi, 1
 Abreaction, 656
 Abreactive treatment, 644
 Absolute judgements of size, 504
 Absolute threshold, 111, 118, 120, 143, 144, 149, 153
 Absorption, 150
 Abstinence syndrome, 656
 Abstract attitude, 541
 Abstract reasoning, 596
 Abstraction, 534, 538, 594
 Abstraction capacity, 582
 Abstraction-concreteness, 533
 Abstraction factor, 535
 Absurdities, 222, 227
 Accessibility, 232
 Accident proneness, 469
 Accuracy, 169, 170, 171, 178, 189, 190, 588, 652
 Accuracy-characteristic, 176
 Accuracy score, 188
 Acetyl-choline, 421, 643, 672, 676
 "Achievement imagery" (A.I) scores, 514
 Acid-base balance, 154
 Acidosis, 153
 Acquisition, 779
 Acromegaly, 380
 ACTH, 670
 Action potentials, 662
 Activation, 419, 425
 "Activation theory," 448
 Activity, 312, 749
 Activity level, 24
 Acuity, 149
 Acute anxiety, 22
 Acute schizophrenia, 208
 Adaptation, 116, 155, 418, 425, 430, 431, 433, 436, 438, 440, 443, 445, 446, 457, 757
 Adaptive flexibility, 238
 Addiction, 199, 644, 656, 664, 744
 Addition, 670
 Adipose tissue, 360, 366
 Adjective check-list, 656
 Adjustment, 70, 71, 73, 274, 399, 407
 Adjustment syndrome, 42
 Adolescence, 364
 Adolescent growth spurt, 362, 364
 Adoption, 322
 Adrenal cortex, 288, 623
 Adrenal cortical insufficiency, 154
 Adrenal corticoids, 366
 Adrenal gland, 312, 619
 Adrenaline (*see also* epinephrine), 146, 154, 477, 639, 671, 672, 673, 675, 676, 678, 681, 735, 740
 Adrenaline level, 623
 Adrenochrome, 678, 681
 Adrenolutin, 678
 Adrenoxine, 678
 "Aeroneuroses," 154
 Aesthetic intelligence, 376
 Aetiology, 1, 488
 Affect, 244
 Affective changes, 578
 Affective discrepancy, 285
 Affective disorders, 209, 219
 Affective psychoses, 197, 198, 328, 621
 After-image effect, 109, 155
 After-image latency, 156
 Age, xiv, 747
 Age differences, 37
 Age factor, 556
 Aggression, 271, 404, 407
 Aggressive behaviour, 6, 399, 745, 746, 750
 Aggressiveness, 304, 312
 Agitation, 575, 755
 Agnosias, 547
 Agranulocytosis, 682
 Aiming, 33
 Air blast, 745
 Alarm, 619
 Albino, 309
 Alcohol, 133, 146, 152, 153, 156, 471, 473, 477, 480, 567, 634, 637, 644, 645, 660, 661, 664, 665, 669, 670, 671, 676, 740, 742, 744
 Alcoholic addiction, 312
 Alcoholic cirrhosis, 147
 Alcoholics, 208, 210, 323, 676
 Alcoholism, 321, 479, 664, 744
 Alkalosis, 153
 Allele, 302
 Allergies, 477
 Alpha-naphthylthiourea, 750
 Alpha rhythm, 470, 599
 Alsatian, 736, 739
 Alternating current, 612
 Alternation behaviour, 474
 Alternation tests, 45
 "Altitude" (of tests), 169
 Alzheimer's disease, 305
 Ambiguous-input (to problem solver), 175-92
 Ambiguous stimulation, 753
 Ambivalent stimuli, 754
 Amelioration rate, 710
 Aminopyrine, 641
 Ammons Full Range Picture Vocabulary, 205
 Ammons Pathways Test, 519
 Amnesias, 578, 614, 622, 625, 657
 Amnesic aphasia, 537
 Amobarbital tests (*see also* amylobarbitone), 658
 Amoeba, 748
 Amphetamines, 133, 146, 472, 618, 641, 642, 643, 645, 649, 650, 663, 681
 Amphetamine sulphate (*see also* benzedrine), 646, 647
 Amylobarbitone, 641, 642, 655, 656, 682
 Amylobarbitone sodium (*see also* Sodium Amytal), 645, 648, 655, 656
 Amytal (*see also* amylobarbitone), 655, 656, 657, 660, 661, 662, 663
 Anabolic biotype, 367
 Anaemia, 154
 Anaesthesia, 460, 473, 618, 642, 656
 Anaesthetics, 641, 663
 Anal character, 407
 Anal phase, 403, 407
 Analeptics, 641
 Analgesics, 641, 670
 Analogies tests, 227, 660
 Analysers, 533
 Analysis, 752
 Anatomical convergence, 540
 Anatomical responses, 583
 Androgens, 367
 Androgyny, 344, 364, 367, 383
 Anger, 419, 674
 Angioscotoma, 151
 Animal hypnosis, 726
 Animal masochism, 742
 Animal's insomnia, 737
 Anorexia nervosa, 154, 720
 Anosognosia, 547
 Anoxia, 122, 124, 125, 141, 142, 145, 146, 149, 150, 152, 153, 154, 155, 156, 670
 Antabuse, 773
 Antecedent probabilities, 771
 Anterior pituitary insufficiency, 154
 Anthropometric, 347, 363
 Anthropometry, 377
 Anthropomorphism, 728
 Anthroposcopy, 357, 363
 Anticipatory displacements, 653
 Anticipatory errors, 647

- Anticipatory goal reaction, 615
- Anticipatory goal response, 193
- Antiepileptics, 641
- Antigenic activity, 477
- Antipyretics, 641
- Antipyrine, 360
- Anxiety, 21, 28, 40, 41, 43, 52, 53, 67, 78, 84, 86, 133, 200, 221, 224, 232, 233, 235, 236, 237, 251, 262, 264, 265, 270, 273, 274, 275, 279, 280, 284, 291, 334, 401, 418, 419, 429, 432, 448, 450, 458, 459, 467, 476, 478, 489, 582, 584, 600, 616, 617, 623, 636, 656, 657, 659, 669, 670, 673, 674, 675, 676, 680, 716, 745, 777
- Anxiety conservation, 490
- Anxiety induced experimentally, 503
- Anxiety neurosis, 199, 207, 291
- Anxiety states, 10, 21, 39, 154, 367, 370, 373, 384, 444, 445, 470, 659
- Aphasia, 234, 475, 534, 543, 544, 546, 554
- Aphasic disturbances, 549
- Aphonia, 657
- Apomorphine, 479, 480
- Apparent movement, 109, 536, 537
- Appetite, 648
- Apprehension, 650
- Approach-avoidance conflict, 617, 744
- Approach-avoidance model, 752
- Apraxias, 547
- Areas (Brodmann), 574, 575, 580
- Arecoline, 471
- Arithmetic ability, 548
- Arithmetic test, 680
- Arithmetic test performance, 679
- Arithmetic reasoning, 666
- Arm-hand steadiness, 33
- Arm length, 350
- Army Alpha test, 199, 224, 624
- Arousal, 419, 425, 428, 440, 441, 448, 450
- Arousal theories, 449
- Arterial blood pressure, 618
- Arterial saturation, 151
- Arterio-sclerosis, 242
- Arterio-sclerotic dementia, 336
- Artificial pupil, 117, 122, 126, 144, 145
- Artistic productions, 69
- Ascendence-submission, 82, 371
- Ascending reticular activating system, 643, 655
- Asphyxia, 397, 398
- Aspirations, 289
- Aspirin, 670
- Assault, 376
- Associated signs, 727
- Associations, 542, 660
- Associationism, 530
- Associative errors, 662
- Associative functions, 652
- Associative inhibition, 598
- Associative interference, 597
- Assortive mating, 317
- Asthenia, 321
- Asthenics, 38, 48, 328, 346, 348, 645
- Asthma, 288, 381, 477, 489, 635, 771
- Asymptote, 519
- Ataractic, 641
- Atarax, 682
- Ataxia, 658, 661, 662
- Athletic, 66, 86, 346
- Atomization, 168
- Atonic, 348
- Atropine, 471, 641, 643, 672, 675
- Attainment discrepancy, 285
- Attention, 53, 111, 251, 516, 648, 660, 679
- Attenuation, 358
- Audiogenic seizures, 312, 614, 617, 726, 748
- Audition, 153
- Auditory distraction, 504
- Auditory feed-back, 67
- Auditory flutter fusion, 21
- Auditory impairment, 543
- Auditory learning, 545, 546, 551
- Auditory modality, 546, 547
- Auditory recognition, 546
- Auditory sensitivity, 667
- Auditory thresholds, 742
- Authoritarian homes, 399
- Authority, 47
- Autistic and communicative gestures, 601
- Autokinesis, 741
- Autonomic activation, 422
- Autonomic balance, 418, 420, 421
- Autonomic drugs, 671
- Autonomic dysfunction, 369
- Autonomic factor, 421
- Autonomic functions, 374, 422, 448
- Autonomic imbalance, 600
- Autonomic lability scores, 424
- Autonomic nervous system, 3, 28, 419, 420, 421, 423, 424, 447, 450, 600, 611, 620, 656
- Autonomic over-reactivity, 21
- Autonomic reactivity, 28, 29, 674
- Autonomic responses, 332, 419
- Auxiliary scientist, 765
- Aversion therapy, 474, 479
- Aversive stimulus, 743, 745, 747
- Avertin, 742
- Avoidance behaviour, 263
- Avoidance learning, 754
- Avoidance reactions, 263
- Azacyclonal, 682
- BABCOCK efficiency index, 226
- Babcock scale, 624
- Babcock test, 204, 206, 209
- Baboons, 589, 591
- Backwardness, 394, 398
- Ballistocardiogram, 674
- Band-width (of comparator), 186
- Barbiturates, 133, 156, 634, 639, 641, 642, 643, 654, 655, 656, 663
- Barbiturate anaesthesia, 644
- Barbiturate sensitivity, 661
- Barognosis, 548
- Basal metabolism, 227
- Base rates, 771
- Beagle, 739
- Behaviour disorders, 327, 726
- Behaviour problems, 229
- Behaviour-problem children, 398
- Behaviour therapy, 26, 775, 778
- Behavioural oscillation, 597, 598
- Behaviourism, 108, 130, 457
- Belle indifférence*, 199
- Benactyzine, 682
- Bender Gestalt Test, 76, 77, 78, 221, 680
- Benjamin Proverbs Test, 243, 249
- Bunsen-Roscoe law, 134
- Benton Test of Visual Retention, 597
- Benzedrine, 591, 600, 643, 648, 651
- Benzhydrol, 653, 682
- Bernreuter Scale, 645

 Uniovar twins, 323
 Unitary theory of brain functioning, 534
 Unitary views, 557
 Unsatisfactory homes, 401
 Unstressed testing, 187, 189
 Unreality, 221
 Untimed tests, 170
 Unusual stimuli, 730
 Ultrasonic irradiation, 569
 Urea, 655
 Urinary secretions, 477
 Urinating, 739
 Urine-alcohol, 699
 U.S.E.S. battery, 41

 VACCINATION, 2
 Vagal tonus, 421
 Vagotonia, 645, 675
 Validity, 320, 371, 767
 Validity scale K of the M.M.P.I., 500
 Variability, 37, 66, 75, 82, 91, 94, 95, 194, 210, 211, 214, 669
 Variability of judgement, 65
 Variance (of response times), 172, 174-76, 182-84

Varying intervals after cerebral excisions, 592
 Vascular system, 622
 Vasoconstriction, 433
 Vasodilatation, 433
 Vasomotor functions, 431
 Vasomotor reactions, 432
 Vasospasm, 618
 Vaso-spastic episodes, 553
 Vegetative system, 367
 Verb-adjective quotient, 67
 Venous ligation, 574
 Verbal analogies, 219, 231
 Verbal comprehension, 241
 Verbal conditioning, 468, 522
 Verbal deficits, 542
 Verbal factor, 637
 Verbal-performance discrepancy, 554
 Verbal and performance tests of intelligence, 769
 Verbal summator, 221
 Verbal tests, 547
 Veridical report, 267
 Vicarious functioning, 555, 556
 Vigilance, 21, 265, 272, 648, 738, 753
 Vigotsky test, 240, 241, 244
 Vineland Social Maturity Scale, 332
 Violence, 329
 Viscerotonia, 370
 Visual acuity, 116, 119, 121, 156, 667
 Visual agnosia, 548
 Visual cortex, 152
 Visual discrimination, 550, 592
 Visual discriminative learning, 546
 Visual dysfunctions, 548
 Visual functions, 549
 Visual learning, 546, 626
 Visual pathways, 133, 138, 148
 Visual perception, 155, 537, 538, 660
 Visual pigment, 121, 138, 140, 150
 Visual psychophysics, 155,
 Visual reception, 109
 Visual space perception, 155
 Visual system, 153
 Visual thresholds, 274
 Visualization, 637
 Visuo-constructive ability, 546
 Visuo-spatial tasks, 547
 Vitality, 309
 Vitamin A, 119, 139, 147
 Vitamin-A deficiency, 155
 Vocabulary, 204, 205, 206, 207, 208, 213, 215, 219, 224, 232, 234, 239, 244, 371, 372, 376
 Vocabulary inflexibility, 68
 Voice, 65
 Volume plethysmography, 431
 Voluntary strength, 88
 Volunteers, 636

 'w' FACTOR, 47
 w score, 583
 W.I.S.C. vocabulary test, 331
 War neuroses, 704
 Wartegg Zeichentest, 73
 Watch-keeping tasks, 510
 Water-jar test, 238
 Water-maze, 615, 616
 Water supply, electrified, 749
 Weaning, 6, 406

- Weber-Fechner law, 113
 Wechsler-Bellevue scale, 23, 73, 197, 198, 199, 202, 203, 205, 210, 212, 213, 214, 215, 222, 226, 227, 231, 233, 235, 595, 680
 Wechsler-Bellevue Deterioration Index, 204, 206
 Wechsler Memory Scale, 234, 597, 624
 Weight, 350, 352, 357, 361, 362, 375, 469, 634, 682
